In intra-abdominal and gynecologic infection due to indicated organisms

P 24,798

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, [illegible]) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

* Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

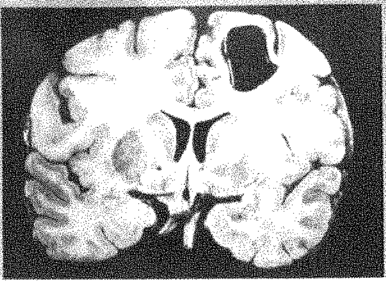
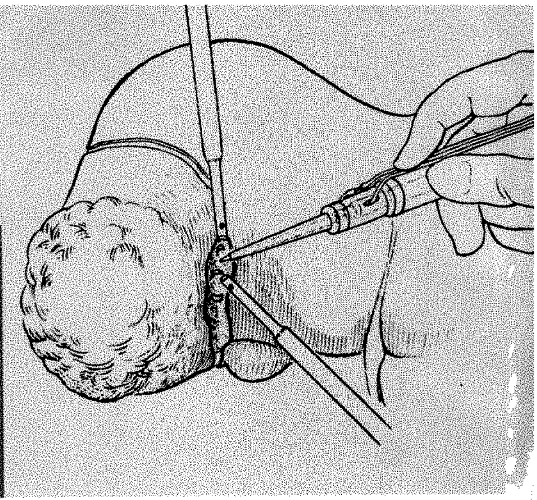
Now...the new book that shows you the role of surgical resection in the curative treatment of metastatic cancer





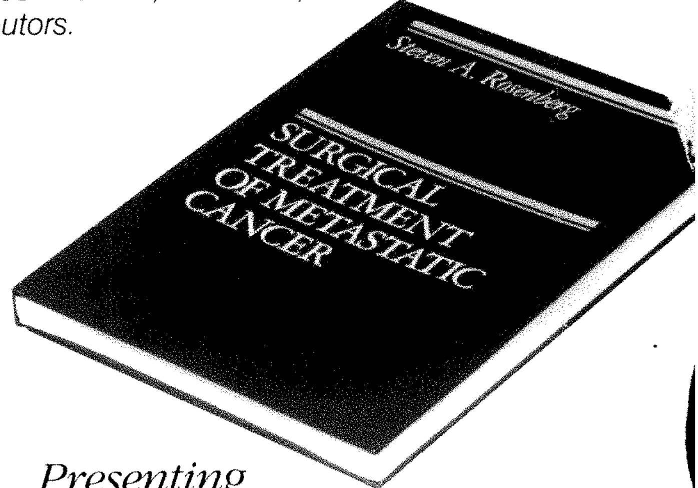
SURGICAL TREATMENT of METASTATIC CANCER

Edited by Steven A. Rosenberg, M.D., Ph.D.

Chief of Surgery, National Cancer Institute, Bethesda, MD.

9 contributors.

> *❝ For many patients with isolated visceral metastases from solid tumors, surgical resection of those metastatic deposits represents the best opportunity for cure. For patients with solitary pulmonary and hepatic metastases, up to 30% of patients may experience prolonged disease-free survival after metastasectomy. Only a small subset of patients with metastatic cancer are likely to benefit from surgical resection and identification of these patients is an important part of the application of this treatment. ❞*
>
> **—from the *Preface***



Taking a bold approach to treatment

Now, for the first time, here is an in-depth resource that describes the role of surgical resection in the treatment of metastatic cancer. Editor Dr. Steven A. Rosenberg, Chief of Surgery at the National Cancer Institute, and a leading figure in cancer research and treatment, poses the premise that the role of surgical resection in treating metastatic cancer has indeed been underappreciated. He and a distinguished group of contributors have designed this book to present the essential information oncologists and surgeons need to understand the value of this treatment.

Presenting a highly significant option

Detailed information is presented concerning:

- the modern understanding of the biology of the metastatic process
- up-to-date techniques for the diagnosis of lung, liver, and brain metastases
- indications for and results of the surgical resection of lung, liver, and brain metastases
- the indications for lymph node dissection in the treatment of cancer.

286 pages. 120 illustrations. 68 tables. 1987. $59.50

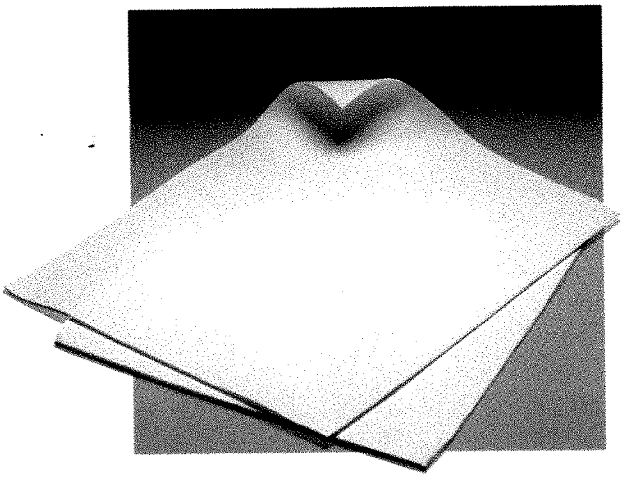
The Natural Choice



The best is not always good enough. The first choice, a patient's own tissue, cannot always be used for surgical reconstructions. When this happens the Soft Tissue Patch becomes the natural choice.

Since its introduction five years ago, the Soft Tissue Patch has performed exceptionally well in over 12,000 clinical cases. These cases include a wide variety of applications:

- Abdominal wall defects
- Large and small hernia repairs
- Thoracic wall defects
- Related pediatric reconstructions
- Rectal prolapse
- Vaginal prolapse
- Gastric banding

The excellent performance of the Soft Tissue Patch is due to its:

- soft, conformable nature
- high, balanced strength
- resistance to the spread of infection
- biocompatibility
- lower incidence of visceral adhesions/tissue erosion

GORE-TEX Soft Tissue Patch, the superior biomaterial, the natural choice.

For more information, return the business reply card or coupon. To order call 800-638-4804.

Oncology Fellowships At NIH

The National Cancer Institutes, National Institutes of Health, Public Health Service, is accepting applications for fellowships in oncology. Positions are available to physicians who have completed at least two years of training in internal medicine, pediatrics, or surgery.

The medical oncology training program offers 3-year fellowships beginning July 1, 1988 and July 1, 1989. This 3-year program consists of one year of primary clinical responsibility on the medical oncology, pediatric oncology, and radiation oncology services of the National Cancer Institute. The second and third years consist of an individualized program of laboratory research and clinical investigations and continued outpatient clinical experience. Fellowships satisfy subspecialty Board requirements for Medical Oncology and Pediatric Hematology-Oncology.

The Surgery Branch offers a two-year surgical oncology fellowship program beginning July 1, 1988 and July 1, 1989. This program consists of 6 months of patient care and 1-½ years of laboratory research with the senior staff of the Surgery Branch. A third year of continued laboratory experience is available to selected Fellows.

Emphasis is placed on continuity of patient care, principles of patient management, and design and conduct of clinical trials. Seminars, lectures and conferences deal with a variety of related subjects including biostatistics, immunology, epidemiology, cell biology, cell kinetics, molecular biology, virology, genetics, clinical pharmacology, diagnostic pathology, and radiobiology.

The laboratory aspects of the program are directed at training Fellows to become independent investigators. Topics under study include cell kinetics, endocrine aspects of cancer, clinical pharmacology of antineoplastic agents, tumor immunology, cell biology and molecular biology, viral oncogenesis, hematopoietic differentiation and genetics. In addition, there is ample opportunity for participation in clinical investigations. Medical Staff Fellows will be assigned to Civil Service positions with an annual salary of $30,000 and an increase of $2,000 for each additional year up to a maximum of $34,000. Medical Staff Fellows will receive all benefits including health insurance, life insurance options, vacation and sick leave. In addition, moving, travel expenses for the Fellow and Federal health care benefits are available. For further information and application procedures, please contact:

NATIONAL INSTITUTES OF HEALTH

THROMBOSTAT™ (THROMBIN, USP), a trusted hemostatic aid, is now available in a pump spray form—permitting flexible and easy application. With the new THROMBOSTAT pump, you can achieve hemostasis in seconds over large body surface areas. Each depression of the pump offers an even distribution

SPRAY ON HEMOSTASIS

of THROMBOSTAT solution—allowing uniform hemostasis of the total area. The THROMBOSTAT pump is available in a convenient sterile kit that features a 20,000-unit vial of THROMBOSTAT (a practical size for procedures involving capillary bleeding), an appropriate measure of diluent, and a pump sprayer cap. The kit offers sterile packaging—permitting the entire contents to be brought directly into the sterile field. With the new THROMBOSTAT kit, it has never been simpler to control capillary bleeding.

Please see next page for brief summary of prescribing information.

THROMBOSTAT™ (THROMBIN, USP) (Bovine Origin)

Before prescribing, please see full prescribing information. A Brief Summary follows:

Thrombostat must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE: Thrombostat (Thrombin, USP) is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery solutions of Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS: Thrombostat is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING: Because of its action in the clotting mechanism, Thrombostat must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Thrombostat is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS: General: Consult the absorbable gelatin sponge product labeling for complete information for use prior to utilizing the thrombin-saturated-sponge procedure.

Pregnancy—Teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical (Bovine). It is also not known whether Thrombin, Topical (Bovine) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical (Bovine) should be given to a pregnant woman only if clearly indicated.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: An allergic type reaction following the use of Thrombostat for treatment of epistaxis has been reported. Febrile reactions have also been observed following the use of Thrombostat in certain surgical procedures but no cause-effect relationship has been established.

DOSAGE AND ADMINISTRATION: General: Solutions of Thrombostat may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc, solutions containing approximately 100 units per ml are frequently used. For this, 10 ml of diluent added to the 1000 unit package is suitable. Where bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1000 to 2000 units per ml may be required. For this the 5000 unit vial dissolved in 5 ml or 2.5 ml respectively, of the diluent supplied in the package is convenient. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate volume of diluent. In many situations, it may be advantageous to use Thrombostat (Thrombin, USP) in dry form on oozing surfaces.

Caution: Solutions should be used the day they are prepared. The solution may be used for up to 6 hours when stored at room temperature; up to 24 hours when stored under refrigeration, and, if necessary, up to 48 hours when stored frozen.

The following techniques are suggested for the topical application of Thrombostat.

1. The recipient surface should be sponged (not wiped) free of blood before Thrombostat is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the Thrombostat mixes freely with the blood as soon as it reaches the surface.
3. In instances where Thrombostat in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried Thrombostat is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place.

Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP as follows:

1. Prepare Thrombostat solution of the desired strength.
2. Immerse sponge strips of the desired size in the Thrombostat solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

Thrombostat Kit: Thrombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. The Kit may be used as follows:

1. Remove the Tyvek blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared and the pump sprayer cap inserted and seated on the Thrombostat solution vial. Note: Several strokes of the pump sprayer will be required before the Thrombostat solution is expelled.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

THE BILLINGS CLINIC

Certified Cardiopulmonary Perfusionist

Progressive medical center in the Northwest area is seeking a certified Cardiovascular Perfusionist. Qualifications: Applicant must be certified or eligible for certification as a Perfusionist; licensure as a registered nurse is helpful but not required; demonstrated ability to work effectively with cardiovascular team. Salary commensurate with experience, excellent benefits.

Forward resume to:

Personnel Manager
The Billings Clinic
P.O. Box 35100
Billings, MT 59107-5100.

General Surgeon
New York State
Capital Region

Community Health Plan is looking for a Board Certified/Board Eligible General Surgeon to be the fifth member of our active General Surgery Department. A progressive medical staff is the heart of our well-established, quality-oriented, multi-specialty HMO.

Location near Albany New York, the area offers a wide variety of educational, cultural and recreational opportunities and affords easy access to Boston, Montreal and New York City.

We offer competitive salary and benefit package including full malpractice, life and disability insurance, a retirement bonus and generous vacation and CME time.

An interest in Vascular Surgery is desirable but not essential.

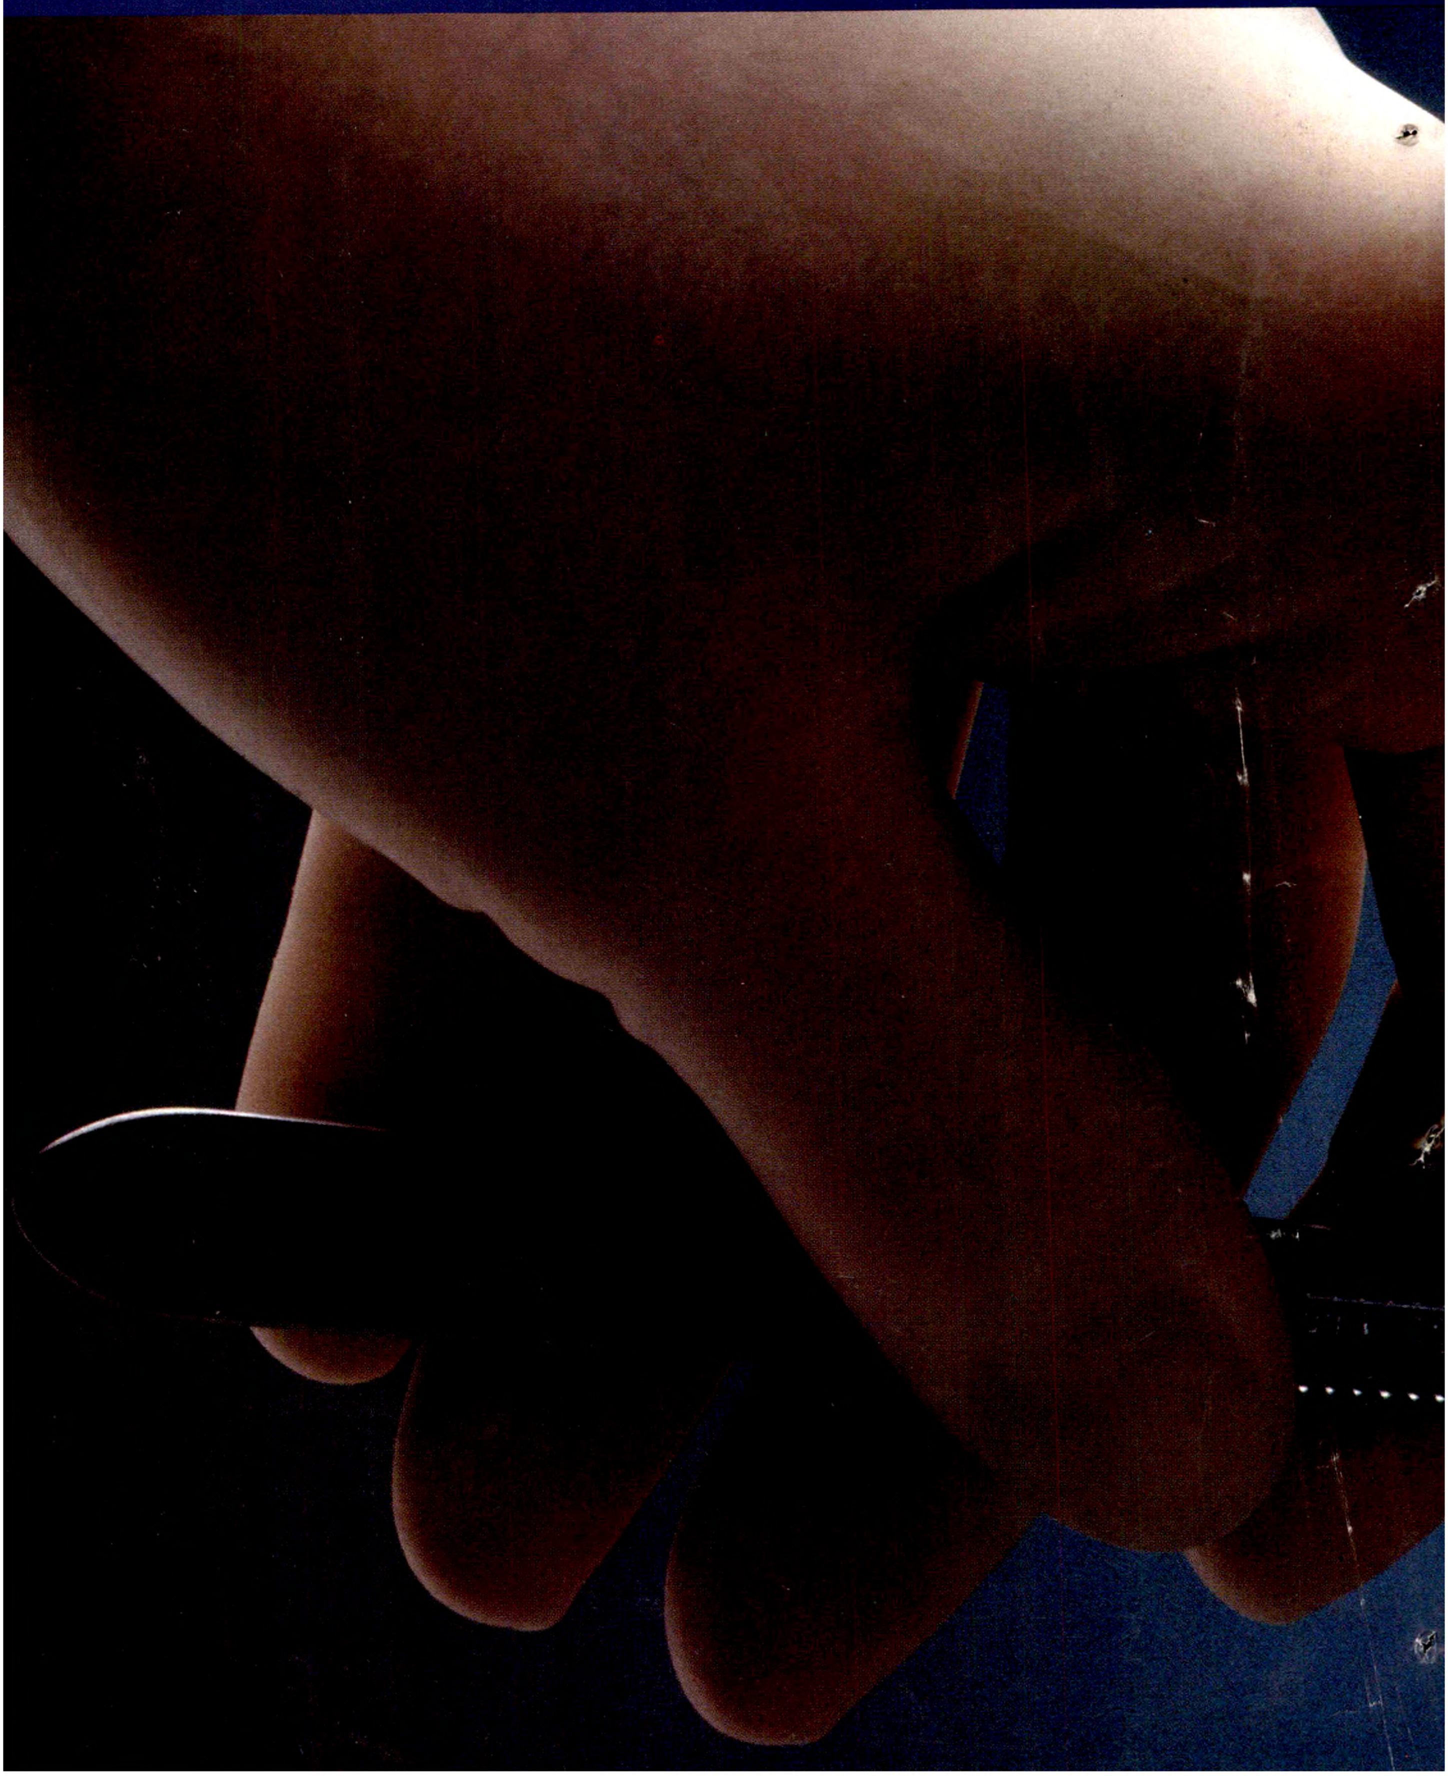
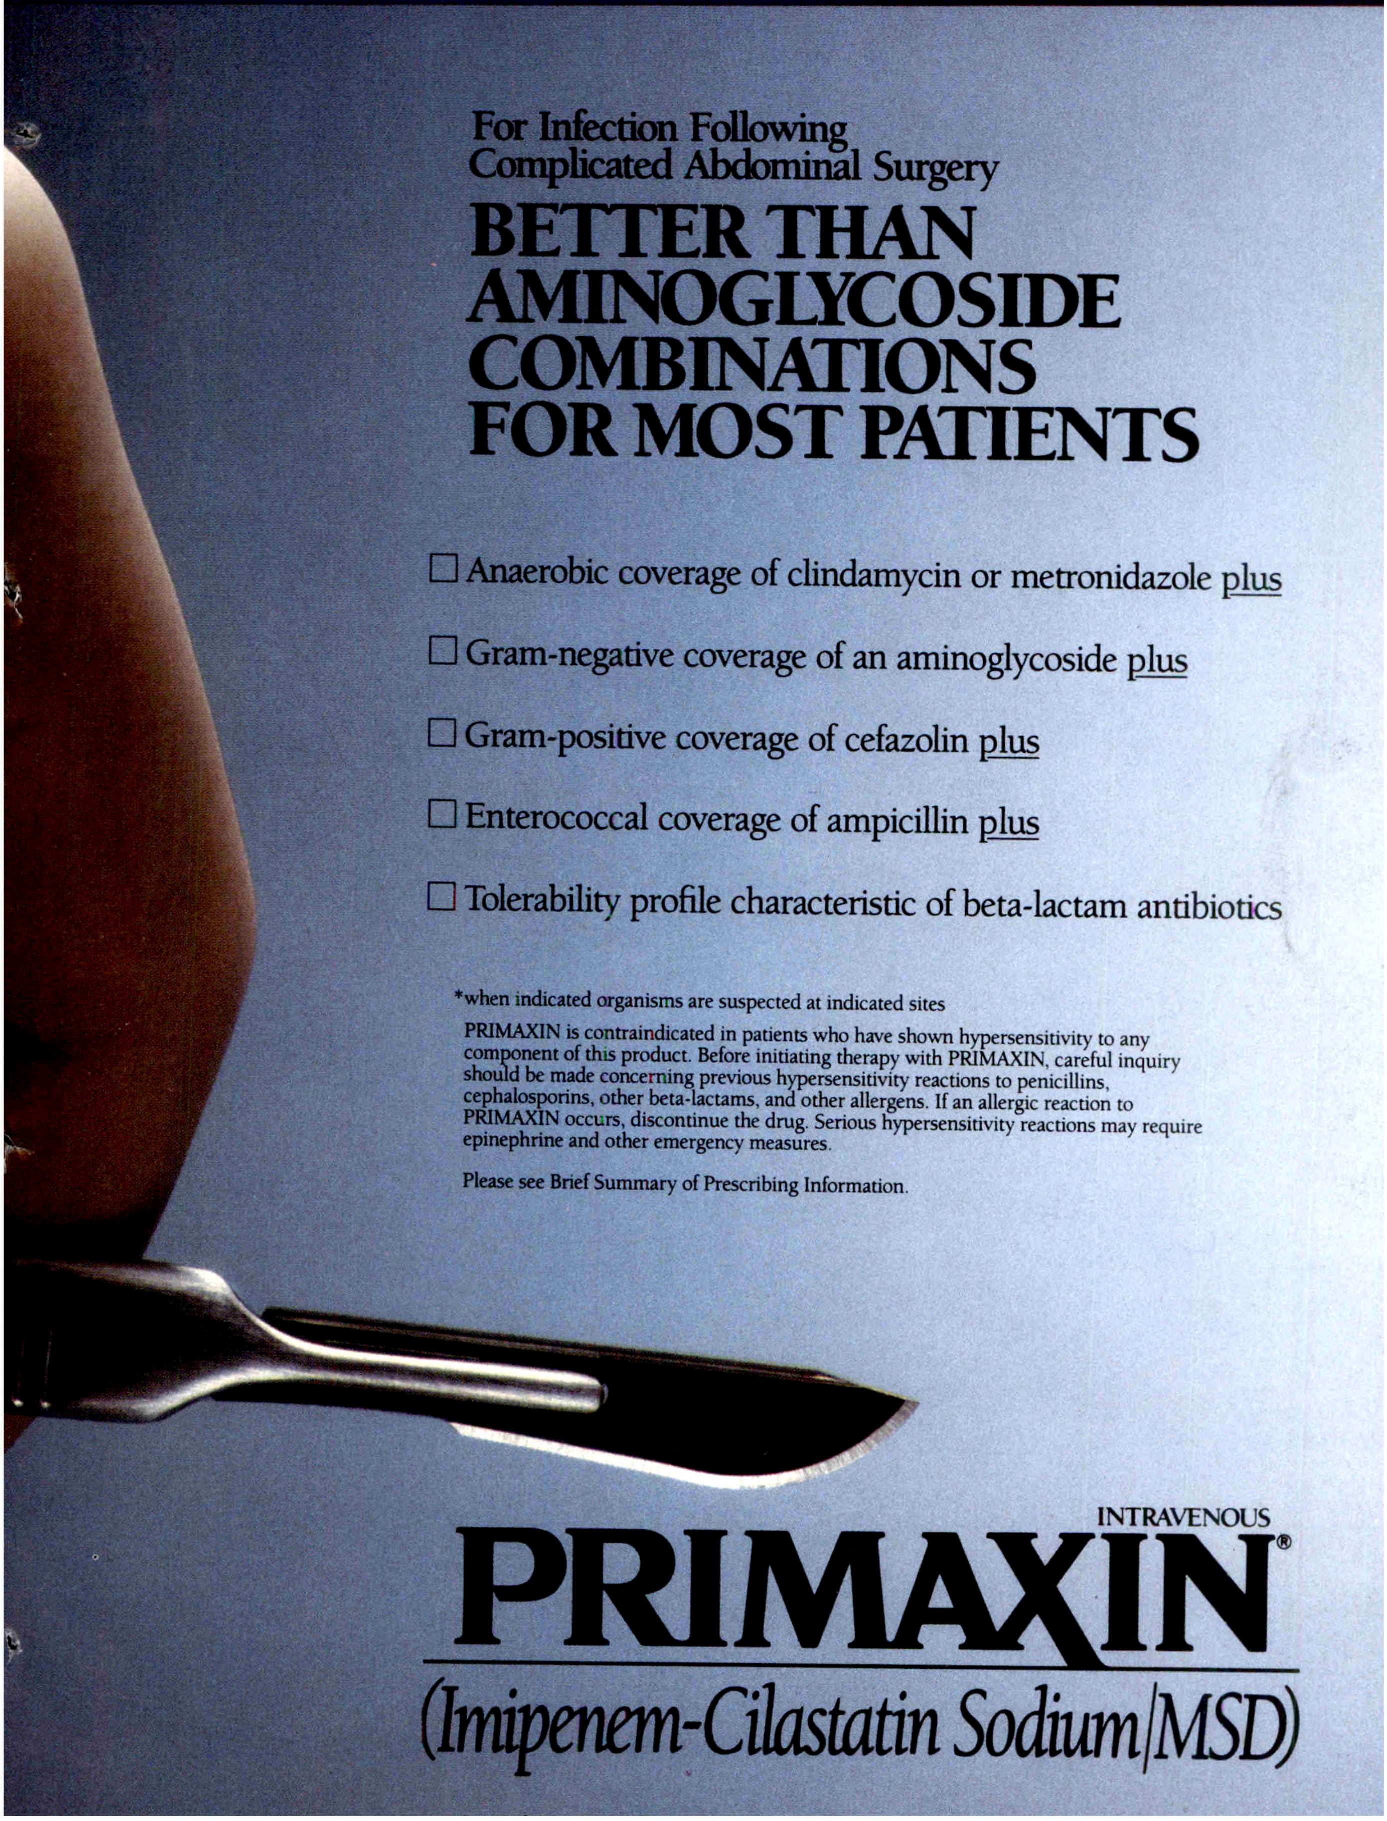
DEFINING A NEW STANDA



RD FOR EMPIRIC THERAPY



For Infection Following
Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

- ☐ Anaerobic coverage of clindamycin or metronidazole plus
- ☐ Gram-negative coverage of an aminoglycoside plus
- ☐ Gram-positive coverage of cefazolin plus
- ☐ Enterococcal coverage of ampicillin plus
- ☐ Tolerability profile characteristic of beta-lactam antibiotics

*when indicated organisms are suspected at indicated sites

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

Please see Brief Summary of Prescribing Information.

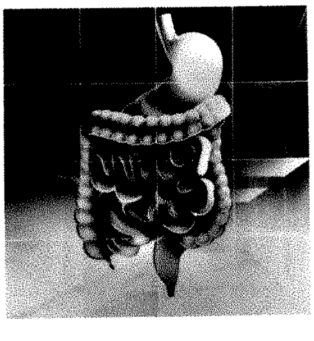
INTRAVENOUS
PRIMAXIN®
(Imipenem-Cilastatin Sodium|MSD)

DEFINING A NEW STANDARD[*] FOR EMPIRIC THERAPY

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium|MSD)



Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN', CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of ≤ 5 mL/min/1.73 m^2 should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

Pregnancy—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in non-pregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Renal*—oliguria/anuria, polyuria; *Skin*—erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage®[†] vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

The Kaplan and Meier and the Nelson Estimate for the Probability of Ulcer Recurrence 10 and 15 Years after Parietal Cell Vagotomy

SØREN MEISNER, M.D., LARS NANNESTAD JØRGENSEN, M.D., and HANS-ERIC JENSEN, M.D., PH.D.

From the Surgical Department 1, Kommunehospitalet, Copenhagen, Denmark

The use of a nonparametric estimate from incomplete observations is demonstrated on ulcer recurrence 10–15 years after parietal cell vagotomy in 339 patients with duodenal ulcer. The median period of observation was 108 months (range: 1–197 months). Proven recurrent ulcer developed in 62 patients. The life-table method as described by Kaplan and Meier and Nelson's modification are demonstrated. The calculated risk of recurrence after 10 years was 23% (±3.8%) and after 15 years was 27% (±4.3%). The rate of recurrence seemed to decline toward the end of the trial time.

NONPARAMETRIC ESTIMATION from incomplete observation is often used in clinical trials that study time until death (clinical trials of cancer therapy). It is, however, equally relevant to use the estimate in trials that study time until other types of untoward events.

Medical follow-up trials often deal with incomplete follow-up data due to either accidental or controlled losses. Complete follow-up data on all patients is the ideal situation and would give the true rate of the event studied. The major advantage of nonparametric estimation from incomplete observation is that the method makes it possible to use all information from the trial accumulated up to the end of the study.

This paper presents the use of nonparametric estimates from incomplete observation and demonstrates the results from the same study, first followed for 10 years and then again after 15 years.

Patients and Methods

In January 1969, parietal cell vagotomy without drainage was first introduced as the surgical treatment of patients with a duodenal ulcer.[1,2] In 1983, we reported the follow-up results, 2–12 years after surgery, of the patients in the Copenhagen study.[3] In the current study we extended the follow-up period of the same patients, all treated between 1969 and 1979.

Three hundred fifty patients had elective parietal cell vagotomy because of a chronic ulcer located in the duodenal bulb, the pylorus, or the prepyloric area. Information concerning operative technique, acid secretion test,

9	6	0.167	0.392	0.656	0.23	0.151

distribution of age, sex, and site of ulcer is previously described.[3] All patients without known recurrent ulcer were traced *via* the National Register, and follow-up examination was done between April 1985 and May 1986.

Eleven patients were excluded from the analysis owing to a lack of follow-up information. Thus, a total of 339 patients remained for the analysis. After completion of the follow-up examination, seven patients did not respond, but using the Kaplan and Meier estimate, these patients are included using the previous known time of follow-up examination.

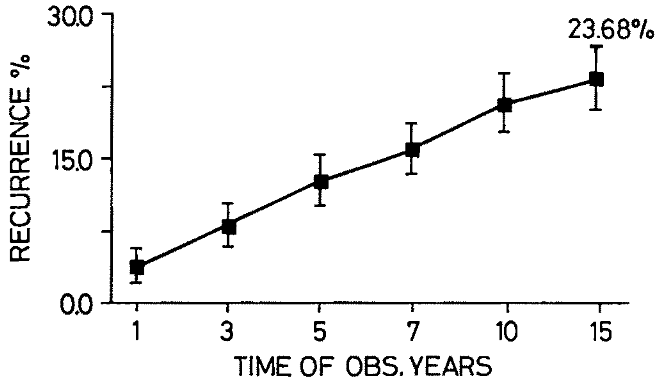

FIG. 1. Probability of ulcer recurrence after parietal cell vagotomy. Kaplan-Meier plots ± 1 SD.

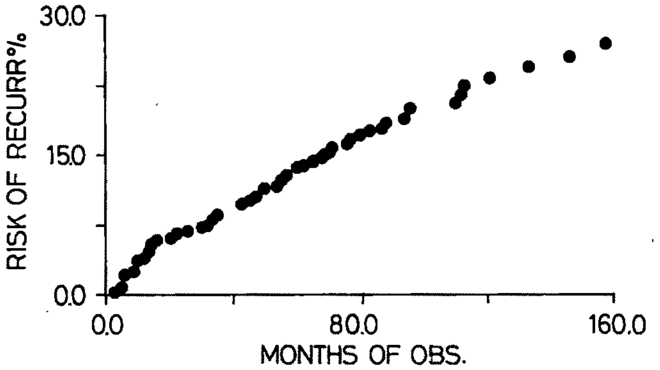

FIG. 2. Integrated recurrence risk after parietal cell vagotomy. Nelson plots ± 1 SD.

Clinical Follow-up

All patients alive without known recurrence with follow-up information of longer than 3 months were sent a similar questionnaire as at the 1981 follow-up examination. Primary nonresponders were sent a additional questionnaire. Secondary nonresponders were, if possible, contacted by telephone. Reports on examinations for ulcer symptoms by general practioners or hospitals were obtained. The median observation time was 108 months (range: 1–197 months).

Statistical Analysis

The ulcer recurrence probability was calculated with due regard to the incomplete follow-up information. The actuarial or life table method as described by Kaplan and Meier[4] was used. Since it is more common to speak of the risk of ulcer recurrence than the freedom from recurrence, data are given as the probability of ulcer recurrence within a given period.

To demonstrate a possible variation in the risk of recurrence over a short period, Nelson's modification of the actuarial method[5] was used. This gives the integrated ulcer recurrence rate as a function of time.

References describing nonparametric estimate for incomplete data are given,[4–7] but to show how simple the analysis is and at the same time perhaps to enable physicians who do not have statistical training to use the method, the method of analysis used for this paper is depicted in Table 1.

TABLE 2. *The Kaplan and Meier and Nelson Estimates for Ulcer Recurrence after Parietal Cell Vagotomy for the 1981 and 1986 Follow-up Study*

	1981	1986
Kaplan and Meier estimate		
10 years	23.76 ± 4.38	20.85 ± 3.03
15 years	?	23.68 ± 3.33
Nelson estimate		
10 years	26.76 ± 5.78	23.31 ± 3.83
15 years	?	26.92 ± 4.37

Results

Of the 339 patients studied, 62 (18.3%) had an ulcer recurrence. The probability of ulcer recurrence, calculated by means of the acturial method, is shown in Figure 1. After 10 years, the risk of recurrence was 20.85% ± 3.03% (mean ± 1 SD), and after 15 years was 23.68% ± 3.33% (mean ± 1 SD).

The integrated estimate for ulcer recurrence is shown in Figure 2. After 10 years, the risk of recurrence was 23.31% ± 3.83% (mean ± 1 SD), and after 15 years was 26.92% ± 4.37% (mean ± 1 SD). There seems to be a higher risk at the beginning, then almost a constant risk and possibly a slight decline in the recurrence risk toward the end of the trial.

Discussion

The 10-year follow-up examination of The Copenhagen parietal cell vagotomy study[3] and the current 15-year follow-up examination were carried out using the exact same method. The results of both the Kaplan and Meier estimate and the Nelson estimate for recurrence after the two follow-up studies are shown in Table 2. Graphic presentation of the Kaplan and Meier estimate for recurrence after the two follow-up studies is shown in Figure 3. The number of recurrences has risen from 42 (13%) to 62 (18%). In the 1981 study, the actuarial probability of ulcer recurrence after 10 years was 23.76% ± 4.38% and the corresponding integrated risk was 26.76% ± 5.78%. In 1981, the Nelson estimation showed a constant monthly risk of 0.23%, and therefore we could expect a probability rate of approximately 37% after 15 years. However, with additional follow-up study from 10 to 15 years, the estimated probability rate showed a rate of 23.68% ± 3.33%.

The median 1981 observation time was 48 months (range: 1–128 months) and the current 1986 observation time was 108 months (range: 1–197 months), which is reflected in the Kaplan and Meier and Nelson estimates giving smaller standard deviation of mean and therefore a higher accuracy of the estimates of recurrence.

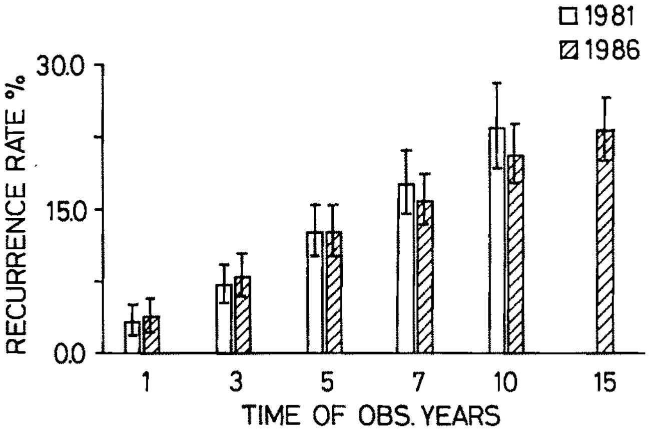

FIG. 3. Probability of ulcer recurrence after parietal cell vagotomy, the 1981 and 1986 follow-up studies. Kaplan-Meier plots ± 1 SD.

The Copenhagen parietal cell vagotomy study has now been followed for a considerably long time. The plot of the Nelson estimates shows the risk of having a recurrent ulcer as a function of time. It seems that the risk is decreasing toward the end of trial time, therefore we can hope that the probability of ulcer recurrence after parietal cell vagotomy without drainage for a chronic duodenal ulcer has reached a stable value of around 25%. However, the final true rate of recurrence can be obtained only with complete follow-up study of all patients. The additional 5 years of trial time from 10 to 15 years has helped us, using the Kaplan and Meier and the Nelson methods to give a more reliable estimate of both the rate and the risk of recurrence.

Incidence of Perforated and Bleeding Peptic Ulcers before and after the Introduction of H2-Receptor Antagonists

ASBJØRN CHRISTENSEN, M.D., RICHARD BOUSFIELD, M.D., and JOHN CHRISTIANSEN, M.D.

From the Department of Surgery D, Glostrup Hospital,
University of Copenhagen, Copenhagen, Denmark

The incidence of perforated and bleeding peptic ulcer requiring emergency surgery was studied in a defined population before and after the introduction of histamine H2-blockers. The incidence of these ulcer complications was unchanged from 1974 to 1984 with an incidence of ulcer perforation from 4 to 10/100,000 per year and of bleeding ulcer from 5 to 10/100,000, indicating that the H2-blockers have not changed the incidence of severe ulcer complications.

FOLLOWING THE INTRODUCTION of H2-blockers in the treatment of peptic ulcer disease, there has been a sharp decrease in elective ulcer surgery.[1-4] The number of operations for perforated ulcer in this period has been almost constant[3,5,6] or slightly decreased,[4,7] although some reports from England and Scotland have shown an increase after 1977.[8,9] The changes in surgery for bleeding gastroduodenal ulcer in this period apparently have not been investigated.

The current study deals with the incidence of surgery for perforated and bleeding gastroduodenal ulcers in a defined population before and after the introduction of histamine H2-blockers.

Materials and Methods

Based on a population of approximately 210,000, the number of operations for perforated and bleeding ulcer from 1974 to 1984 was studied. Cimetidine has been available in Denmark since September 1977. The hospital serves a well-defined area of Copenhagen, and as a result of the organization of the Danish health care and hospital system, all patients from this area are admitted to this hospital for emergency surgical conditions. In the 11-year period under study, the population increased by 7% to 212,010, the number of children (younger than 15 years) decreased from 28% to 20% of the population, whereas the number of persons of 65 years or older increased by 3% to 9.6% of the adult population. Median age for the adult population (≥15 years) increased in the period under study from 37.7 to 40.7 years. The sex ratio was constantly 1:1 throughout the period. To adjust for the demographic changes, operation rates were calculated as the number of operations per 100,000 inhabitants older than 14 years per year. For the age group 15–64 years and for those age 65 or older, the age-specific operation rates were calculated.

For statistical evaluation of differences in operation rates the Mann-Whitney U-test was used; p values less than 0.05 were considered significant.

Results

During the 11-year period, 118 operations for perforated ulcer were performed (Fig. 1). The sex ratio (m:w) was 1.8:1 and the median age was 50 years (range: 22–93 years). No significant change in the operation rates before and after 1977 was found when the material was analyzed as a whole, or when it was analyzed for operations on men and women separately for duodenal and gastric (including prepyloric) ulcers or for age-specific operation rates for patients from 15 to 64 years and for those 65 years or older (Fig. 2).

The annual operation rates for 107 patients who had surgery for bleeding ulcer are shown in Figure 3. The sex ratio (m:w) was 2.5:1, and the median age was 56 years (range: 23–92 years). No significant change was found in the operation rates before and after September 1977. No changes could be demonstrated when the series was divided according to sex, age, and ulcer location (Fig. 4).

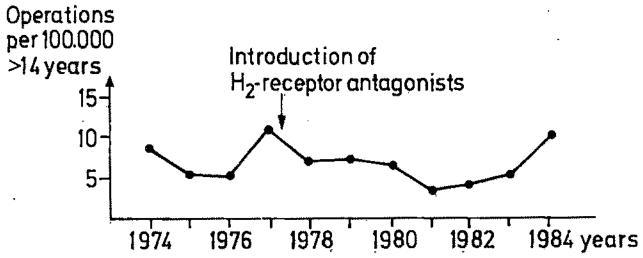

FIG. 1. Operation rates for perforated peptic ulcers from 1974 to 1984. The number of operations per 100,000 inhabitants 14 years or older is reflected.

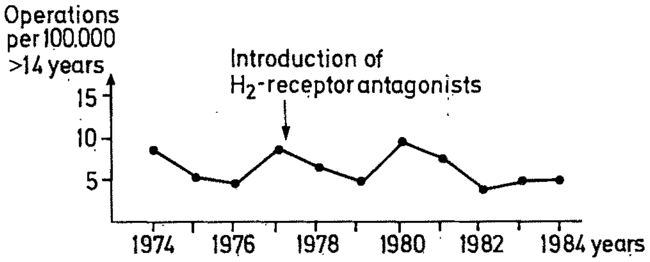

FIG. 3. Operation rates for bleeding peptic ulcers from 1974 to 1984. The number of operations per 100,000 inhabitants older than 14 years is reflected.

Thirteen per cent of patients with perforated ulcer and 43% of patients with bleeding ulcer operated on after 1978 had been treated with cimetidine before admission. Regular use of nonsteroid anti-inflammatory drugs (NSAID) was found in 30% of patients with perforated ulcer before 1977 and in 37% after 1977 compared with 36% and 42%, respectively, of patients operated on for bleeding ulcer ($p > 0.05$).

Discussion

Operation rates for severe ulcer complications, perforation, and hemorrhage were found to be unchanged after the introduction of H2-blockers. Since no changes have taken place in the indications for surgery of bleeding ulcer, the calculated operation rates show the true development in ulcer surgery for perforated and bleeding gastroduodenal ulcers in this period.

Previous studies have shown that almost half of the patients with perforated gastroduodenal ulcers[7,10] and about 20% of those with hemorrhage[11] had an ulcer history of less than 3–4 weeks, which probably explains the findings in the current study that only 13% of patients with perforated ulcer and 43% of patients with bleeding ulcer had received H2-blockers after 1977.

During later years new trends in the occurrence of ulcer complications have become apparent, since there has been an increased number of older patients and of

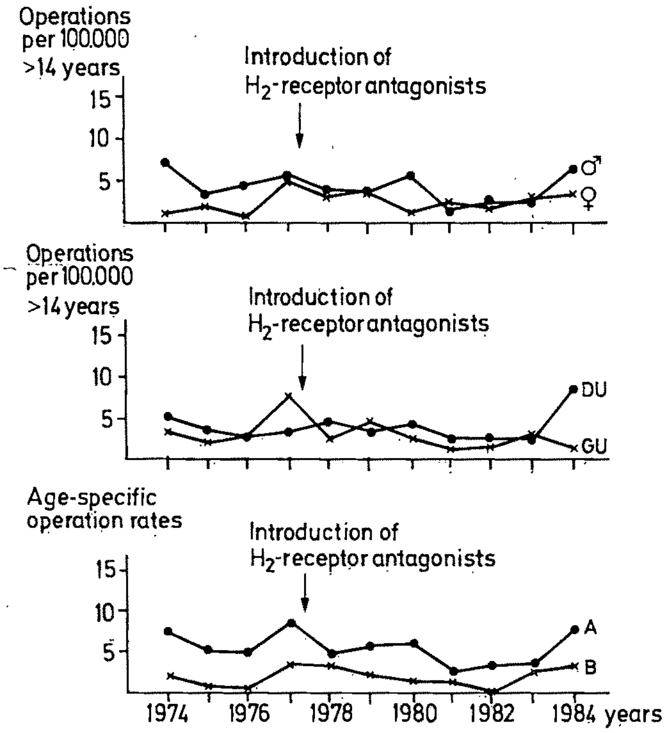

FIG. 2. Operation rates for perforated peptic ulcers from 1974 to 1984 in relation to sex, ulcer location, and age. DU = duodenal ulcer. GU = gastric ulcer. A = operations per 100,000 inhabitants 15–64 years old. B = operations per 100,000 inhabitants older than 65 years.

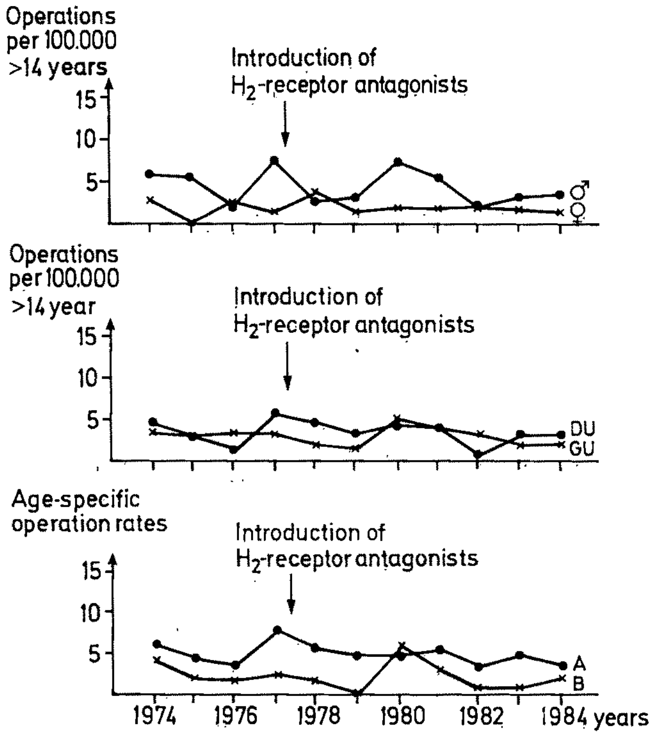

FIG. 4. Operation rates for bleeding peptic ulcer from 1974 to 1984 according to sex, ulcer location, and age. DU = duodenal ulcer. GU = gastric ulcer. A = operations per 100,000 inhabitants 15–64 years old. B = operations per 100,000 inhabitants older than 65 years.

women and a decrease in the incidence of perforation in the younger age groups.[6,12] These trends have been explained by the increasing life expectancy of women as well as by the increase in the use of ulcerogenic antirheumatic drugs especially among elderly women.[5,12] This age and sex difference is not obvious in the current study, although there is a tendency towards a more even sex distribution (2.3:1 before 1977 compared with 1.4:1 after 1977). A similar trend is observed for bleeding ulcer (3.1:1 before 1977 compared with 2.0:1 after 1977).

The use of NSAID is one of the factors generally considered to be of importance in the development of perforated and bleeding ulcers.[5,12–14] The use of NSAID by patients who had emergency surgery for ulcer complications was, however, unchanged in the period under study, and thus cannot explain that no decrease occurred in the incidence of surgery for perforation and hemorrhage. Whether other ulcerogenic factors have changed in this period is uncertain, but can hardly have had more than a marginal influence.

In conclusion, the introduction of H2-blockers has not decreased the incidence of severe ulcer complications requiring emergency surgery, indicating that these drugs probably will have no influence on mortality from peptic ulcer disease.

Zantac®
Injection
Premixed
ranitidine HCl/Glaxo
Premixed 100 ml bag containing 50 mg ranitidine HCl

Convenient

- ☐ Ready to use—no mixing needed
- ☐ Premixed 100 ml bag containing 50 mg ranitidine (as the hydrochloride)
- ☐ No need to refrigerate
- ☐ Stores for 12 to 18 months

Cost-effective

- ☐ Saves pharmacy and nursing time

Raises gastric pH in critical care patients for up to 8 hours*

No significant drug interactions with the hepatic P-450 enzyme system at recommended doses

- ☐ No clinically significant drug interactions between ranitidine and theophylline, phenytoin, or warfarin

*Some patients may require q6h dosing.
See next page for brief summary of Product Information.

Glaxo/ROCHE

ANTAC® Injection **BRIEF SUMMARY**
ranitidine hydrochloride)

ZANTAC® Injection Premixed
ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing informaion in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
NDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated n some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for ive days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Carcinogenesis, Mutagenesis, Impairment of Fertility: There was no indication of tumorigenic or carcinogenic effects in lifespan studies in mice and rats at oral doses up to 2,000 mg/kg/day.

Ranitidine was not mutagenic in standard bacterial tests (*Salmonella, E coli*) for mutagenicity at concentrations up to the maximum recommended for these assays.

In a dominant lethal assay, a single oral dose of 1,000 mg/kg to male rats was without effect on the outcome of two matings per week for the next nine weeks.
Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
Use in Elderly Patients: Ulcer healing rates in elderly patients (65 to 82 years of age) treated with oral ZANTAC were no different from those in younger age groups. The incidence rates for adverse events and laboratory abnormalities were also not different from those seen in other age groups.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC®.

The following have been reported as events in clinical trials or in the routine management of patients treated with oral ZANTAC. The relationship to ZANTAC therapy has been unclear in many cases. Headache, sometimes severe, seems to be related to ZANTAC administration.
Central Nervous System: Rarely, malaise, dizziness, somnolence, insomnia, and vertigo. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.
Cardiovascular: Rare reports of tachycardia, bradycardia, and premature ventricular beats.
Gastrointestinal: Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain.
Hepatic: In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid IV for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.
Musculoskeletal: Rare reports of arthralgias.
Hematologic: Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.
Endocrine: Controlled studies in animals and man have shown no stimulation of any pituitary hormone by ZANTAC and no antiandrogenic activity, and cimetidine-induced gynecomastia and impotence in hypersecretory patients have resolved when ZANTAC has been substituted. However, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.
Integumentary: Rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia.
Other: Rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
NDC 0173-0362-38 2-ml single-dose vials (Tray of 10)
NDC 0173-0363-39 10-ml multi-dose vials (Singles)
NDC 0173-0362-01 2-ml single-dose, prefilled, disposable cartridge-needle units (Tray of 10)
NDC 0173-0362-00 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC® Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

What will you tell her about screening mammography?

Many of your patients will hear about screening mammography through a program launched by the American Cancer Society and the American College of Radiology, and they may come to you with questions. What will you tell them?

We hope you'll encourage them to have a screening mammogram, because that, along with your regular breast examinations and their monthly self examinations, offers the best chance of early detection of breast cancer, a disease which will strike one woman in 10.

If you have questions about breast cancer detection for asymptomatic women, please contact us.

Postoperative Complications and Mortality after Surgery for Gastric Cancer

ASGAUT VISTE, M.D., TROND HAUGSTVEDT, M.D., GEIR EGIL EIDE, CAND. REAL., ODD SØREIDE, M.D., and THE NORWEGIAN STOMACH CANCER TRIAL MEMBERS

Complication rates and postoperative mortality were studied in 1010 consecutive patients entered into the Norwegian Stomach Cancer Trial. Twenty-eight per cent of the patients had one or more complications (31% of the men and 21% of the women). General complications (pneumonia, thromboembolic, and cardiac) were most frequent. The postoperative mortality rate for resected patients was 8.3% (63 of 763). Complication and mortality rates were highest for proximal resections (52% and 16%) followed by total gastrectomy (38% and 8%), subtotal resection (28% and 10%), and distal resection (19% and 7%). By logistic regression analysis it was found that age, sex, operative procedure, prophylactic antibiotics, and splenectomy were significantly related to postoperative complications. The odds ratio for complication for men *versus* women was 1.75: for no antibiotics *versus* antibiotic prophylaxis it was 2.5. Relative to distal resection the odds ratio for complications after subtotal resection was 2.2, for total gastrectomy was 3.9, and for proximal resection was 7.6. Age and sex were the only factors that affected operative mortality. The odds ratio for mortality for men *versus* women was 2.3. The odds ratio for operative mortality was 2.2 when the age of the patient increased with 10 years.

DESPITE IMPROVEMENTS IN diagnostics, pre-, intra-, and postoperative care and surgical technique, the complication rate after surgery for gastric malignancy has virtually remained unchanged during the last two decades.[1-4] Complication rates of 20–40% and hospital mortality rates of 10–33% are commonly reported in Western series,[1,5-7] which contrast a mortality rate of 2–3% reported from Japan.[8,9] It seems that extensive procedures, such as total gastrectomy, carry a higher complication rate than partial resections.[1,3-5] Consequently, the extensive operation must be followed by an improved long-term survival advantage to be justified.

From the Department of Surgery, Section for Medical Informatics and Statistics, University Hospital of Bergen, Bergen, Norway, and the Norwegian Stomach Cancer Trial

Some studies indicate that a survival advantage for extensive gastric resections as compared to less radical procedures may be achieved if the high postoperative morbidity and mortality rates after the former operation can be reduced.[10,11] A reduction in the complication rate may be attained if factors related to complications are identified. So far, little is known about clinical and operative factors related to postoperative morbidity and mortality.

The purpose of this paper was to analyze predisposing factors related to postoperative complications and mortality after gastric surgery for cancer. Further, it was our intention to study a possible relation between complication rates and hospital level to identify the effect of level of care on morbidity and mortality.

Patients and Methods

The Norwegian Stomach Cancer Trial is organized as a prospective observational study with 51 surgical units participating. The patient accrual started September 1, 1982. By December 31, 1984, 1165 patients (705 men and 460 women) had been included. These patients represent 54% of all patients with stomach cancer registered by the Cancer Registry of Norway during the same period. The participating hospitals submitted information on each patient recorded on data sheets to the study headquarters at the University Hospital in Bergen for punching and subsequent analyses.

Of the 1165 patients entered, 1010 (87%; 608 men and 402 women) underwent surgery and 763 patients (65%) had a resection.

No complications	722	72

* Some patients had more than one complication.
† Demonstrated on routine x-ray studies at 5–7 days after operation.
‡ Cardiac, pulmonary, thromboembolism, etc.

Pre- and intraoperative variables that may be related to postoperative complications and mortality were cross-tabulated and analyzed with chi-square statistics. The following factors were considered: age (18–59, 60–69, 70–79, 80–91 years), sex, hospital level (University, County, local), preoperative weight loss (≤5 kp, ≥6 kp), operative procedure, operative evaluation (curative *vs.* palliative resection), splenectomy, prophylactic antibiotics, anastomotic technique (stapler *vs.* hand-sutured), and stage of the disease (TNM classification[12]).

Postoperative mortality was defined as all deaths related to postoperative complications as specified on the registration forms, irrespective of whether the patients died before or after 30 days after operation.

To further analyze interactions between variables related to complications and mortality, we performed a backward stepwise logistic regression analysis,[13] taking into account all possible second-order interactions. By this approach we could study the effect on the dependent variable (*i.e.*, complications and mortality) of one particular variable, whereas all other variables were held constant. Separate analyses were performed with complications and mortality as dependent variables, respectively. The logistic regression analysis was restricted to patients having a resection (763 patients). In the logistic regression analysis, age was included as a continuous variable

The final regression model should fulfill the following three requirements: (1) the model should fit the ob-

served data adequately, *i.e.*, give a Hosmer's test of fit with $p > 0.05$[14]; (2) to adjust for multiple significance testing, a significance level for each variable of 0.01 rather than 0.05 was applied as a stopping criterion,[15] thus reducing the overall probability of Type I error to an acceptable level; (3) the final model should explain the effect of individual variables on complications or mortality in the simplest way (most parsimonious model[16]).

The computations were performed by the BMDP[14] statistical program package implemented on the Univac 1100 computer at the University of Bergen.

Results

Overall Results

The number of complications encountered in the 1010 patients operated on are given in Table 1. The overall complication rate was 28%: 31% for men and 21% for women. General complications (pulmonary, thromboembolic, and cardiac) were most frequently found.

Postoperative complications and mortality according to operative procedure are given in Table 2. The complication rate was highest for proximal resection (52%) followed by total gastrectomy (38%), subtotal resection (28%), and distal resection (19%). The operative mortality for all resected patients was 8.3% (63 of 763): 16% for patients having a proximal resection, 10% following subtotal resection, 8% for total gastrectomy, and 7% for distal resection.

Resected Patients

Patients resected for cure had a complication rate of 30.9% (177 of 573) and a mortality rate of 8.0% (46 of 574) *versus* 31.3% (57 of 182) and 9.2% (17 of 184) for patients having a palliative resection (no significant differences). The tumor stage (TNM classification) did not affect complication and mortality rates (Tables 3 and 4).

Cross-tabulations between postoperative complications and other pre- and intraoperative variables revealed statistically significant associations between the dependent variable complications and age, sex, hospital level, operative procedure, splenectomy, and anasto-

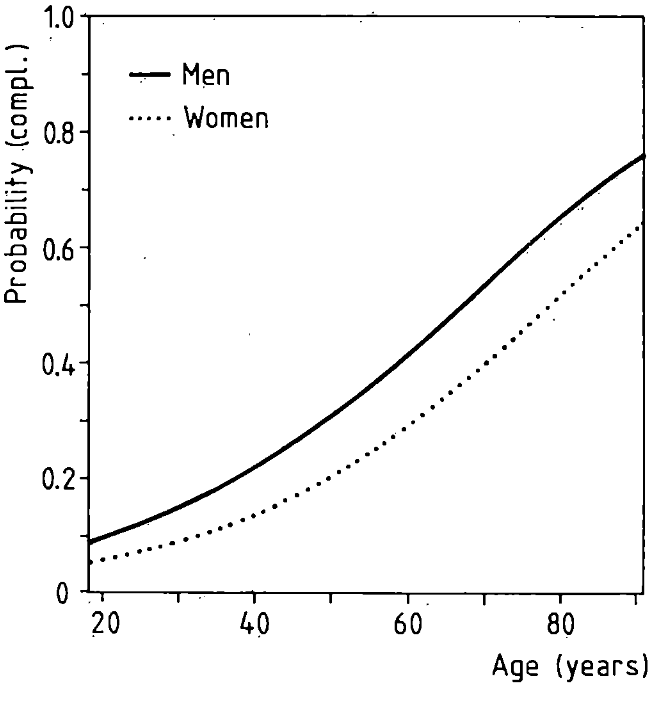

FIG. 1. Probability of postoperative complication for men and women according to age.

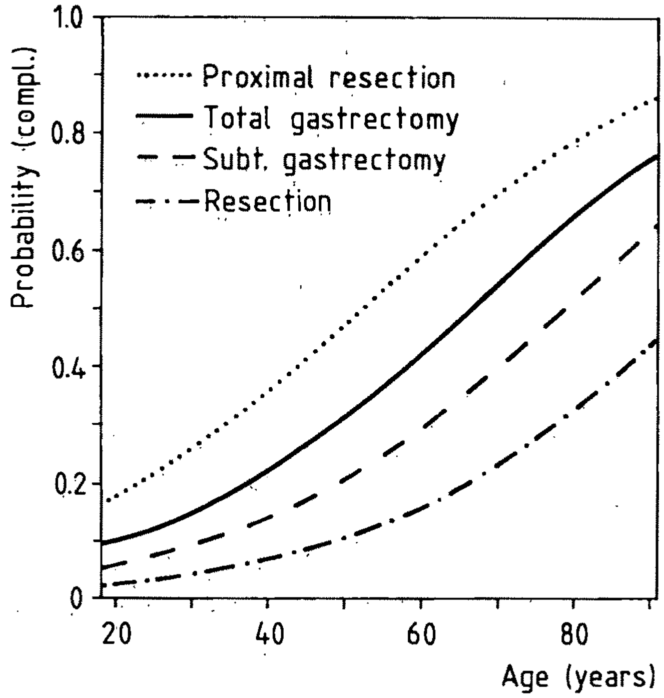

FIG. 2. Probability of complication after various operative procedures *versus* age.

motic technique. Further analyses revealed that age and hospital group were related to operative mortality (Tables 3 and 4).

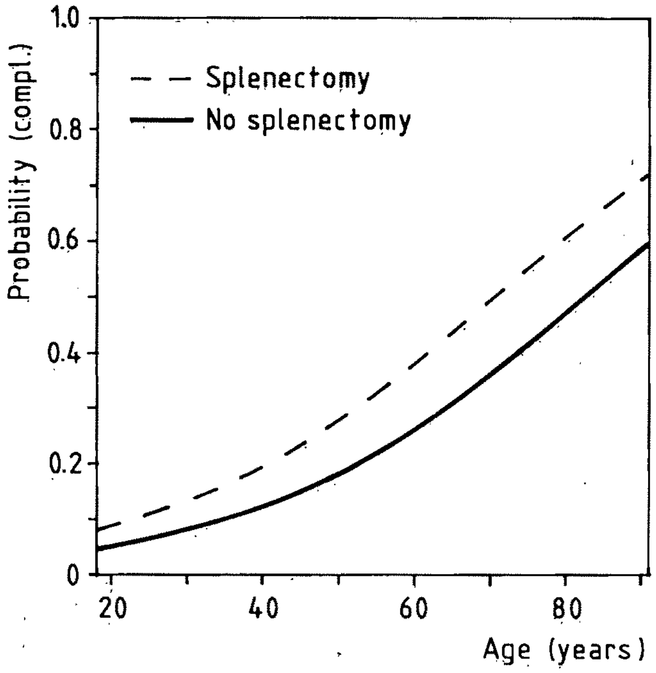

FIG. 3. Probability of complication after concomitant splenectomy *versus* age.

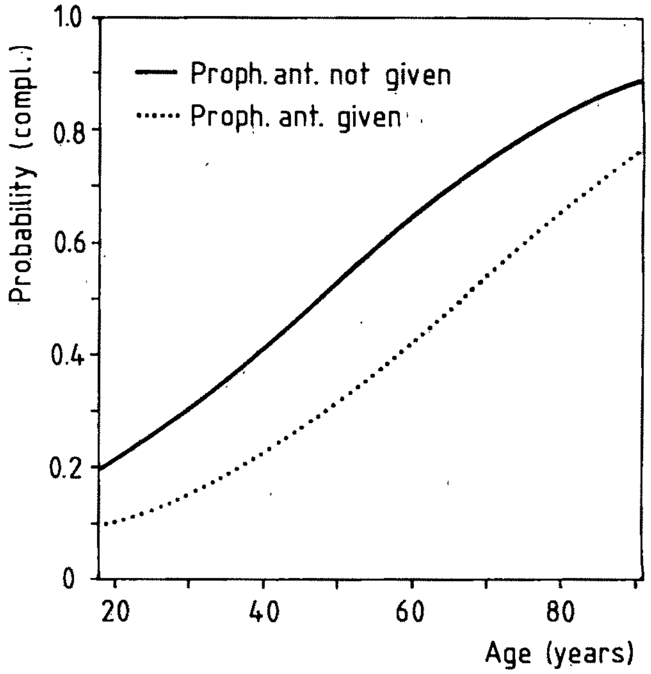

FIG. 4. Probability of complication related to administration of prophylactic antibiotics and according to age.

The final logistic regression model fitted the data well ($p = 0.33$ for goodness of fit). By this analysis we found that complications were significantly influenced by sex, age, operative procedure, prophylactic antibiotics, and splenectomy. Preoperative weight loss, anastomotic technique, operative evaluation, and stage of disease were not associated with complication rate, whereas hospital level was of borderline significance. The odds ratios with 95% confidence intervals and p values are given in Table 5. Men had a higher complication rate than women (estimated odds ratio of 1.75). For operative procedures, the lowest complication risk was found after distal resection, whereas proximal resection carried the highest odds ratio, *i.e.*, 7.2 times higher than the former. Based on the final logistic regression model we plotted the variables operative procedure, prophylactic

antibiotics, sex, and splenectomy against age, and the results are given in Figures 1–4.

The logistic regression analysis was repeated with operative mortality as the dependent variable. The final model (which fitted the data well; $p = 0.43$) revealed that sex ($p < 0.001$) and age ($p < 0.001$) were the only variables that independently influenced postoperative death. The results are visualized in Figure 5. Men had a higher postoperative mortality rate than women. Postoperative mortality increased almost exponentially with age.

Discussion

Several strategies should be explored to improve survival after surgery for gastric cancer. A reduction in operative mortality for patients undergoing a potential curative resection would clearly be beneficial, and interest should be focused on studies aimed at identification of pre- and intraoperative variables which are linked to postoperative complications and mortality. Factors assumed to predispose to complications include technical skill of the surgeon, operating time, malnutrition and age, prophylactic antibiotics as well as operative procedure performed.[17,18]

Most studies on complications after gastric surgery analyze possible predictive factors in a univariate manner, not taking the multivariate nature of this problem into account.[17–20] The limitations of such analyses are illustrated by the two-way cross-tabulations summarized in Table 4, which revealed six factors associated with complications and two related to postoperative mortality. However, the multivariate analyses reduced the number of true significant associations. More importantly, the multivariate analyses also identified variables clearly associated to complications that were not demonstrated by simple cross-tabulation and chi-square statistical analyses, as demonstrated for the variable prophylactic antibiotics (Tables 4 and 5). The reason for this discrepancy might be explained by interactions between the variables. Such findings also suggest that conclusions drawn on the basis of simple cross-tabulations and statistical analyses should be interpreted with care.

Previous studies have shown increasing complication and mortality rates with age,[21,22] whereas others have challenged this finding.[18] In the current study, age was a major determinator with respect to postoperative complication and mortality (Figs. 1–5). Further, men had higher risks than women for all types of complications such as anastomotic leak and bleeding, as well as general complications. A higher postoperative mortality rate for men than for women has also been demonstrated by Miwa,[23] but so far, no hypothesis has been proposed that can explain this finding. Detailed analyses of our data have not uncovered any mechanism that might explain the clear excess risk for men undergoing gastric surgery for cancer.

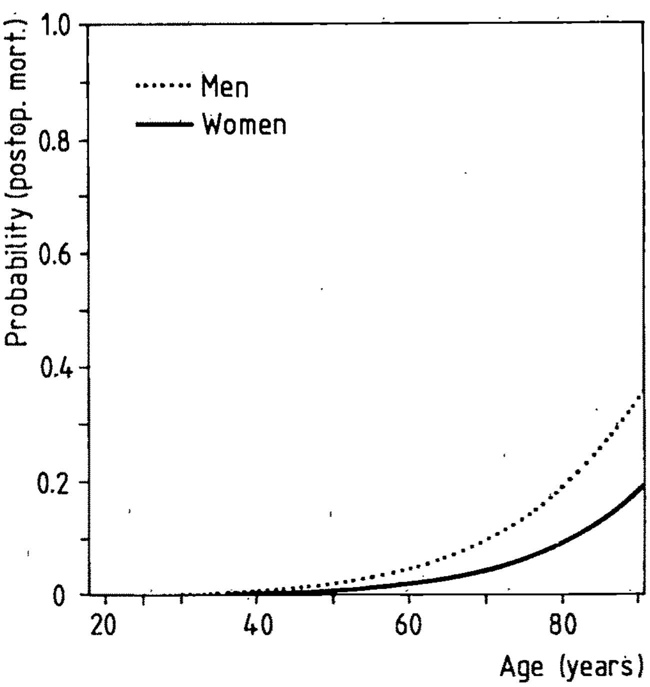

FIG. 5. Probability of operative mortality for men and women according to age.

As reported by others[1,24] we found that the type of operation affected the complication rate, *i.e.*, was higher for extensive procedures (like total gastrectomy) than for distal resection. This is an important conclusion as a potential increase in postoperative long-term survival is expected to follow more extensive operations. However, the survival advantage of an extensive operation performed *de principe* is still a matter of discussion.[25,26]

Some surgeons suggest that a minor surgical procedure as proximal resection for upper-third tumors is the treatment of choice. However, for the last two decades it has been known that proximal resection carries a higher complication rate than total gastrectomy.[1,3,10,24] This finding was confirmed in the current study, which demonstrated alarmingly high complication risks (Fig. 2) for this procedure. It was noted that septic and general complications were especially common after proximal resection. We do not find proximal resection to be any easier to perform than a total gastrectomy, and we recommend the latter procedure for all proximal tumors.

Removal of the spleen *en bloc* with the gastric specimen has traditionally been part of a standard radical gastric resection for cancer. Recently it has been suggested that splenectomy might have a detrimental effect on survival.[27] However, other studies have not been able to confirm the negative effect of splenectomy.[28] In this study we found an increased rate of complication after splenectomy. Whether splenectomy was performed or not did not have any influence on operative mortality.

Administration of prophylactic antibiotics reduced postoperative complications by approximately 10% (Table 3 and Fig. 4). A full discussion about the value of antibiotic prophylaxis in gastrointestinal tract surgery is beyond the scope of this paper. However, based on our data we conclude that any gastric resection for cancer should be covered by prophylactic antibiotics.

Malnutrition has for a long time been recognized to be associated with increased complication and operative mortality rates.[22,29] In this study, weight loss did not have an influence on complications and mortality. The explanation behind this rather controversial conclusion is probably that malnourished patients most often have advanced disease not suitable for resection.

Resection for stomach cancer often implies major surgery for patients at an increased risk. For this reason it might be expected that the level of care would influence patient outcome. We were, however, not able to discover any association between hospital level, complication, and operative mortality. The figures were, however, of borderline significance, with a lower complication rate for county hospitals than for university and local hospitals.

The overall operative mortality rate of 8.3% for resected patients found in this study is in accordance with that of most reported studies from the Western world.[1,2,4,7] Further, it should be noted that the mortality rate after total gastrectomy was comparable to the mortality rate after distal resection (7.7% *vs.* 6.9%). Japanese results are, however, far better,[8,9] and we should aim at reduced operative mortality rates as this will have a substantial impact on long-time survival. The only factors found to predict mortality were sex and age, whereas operative procedure and hospital group were at the borderline of significance.

An Analysis of When Patients Eat after Gastrojejunostomy

DAVID FROMM, M.D., DENNIS RESITARITS, M.D., and ROBERT KOZOL, M.D.

Eighty-five patients who underwent a gastrojejunostomy either alone or in conjunction with vagotomy or gastric resection were evaluated for the day of beginning an oral intake adequate enough to sustain nonoliguric output. This occurred on the average by the seventh to eighth postoperative day, by which time at least 78% of patients were consuming an adequate oral intake. Adequate liquid intake occurred on the average 5.3 days in the absence of vagotomy and 8.8 days in the presence of vagotomy. However, this significant difference is accounted for by the patients who had gastrojejunostomy with vagotomy. Vagotomy with antrectomy, antrectomy alone, and subtotal gastrectomy were not significantly different. The apparent influence of vagotomy on gastrojejunostomy may be due to a type II statistical error. However, 92% of patients who had vagotomy with pyloroplasty consumed adequate liquids by the seventh postoperative day compared with 56% of patients who had vagotomy with gastrojejunostomy.

From the Department of Surgery, SUNY-Health Science Center at Syracuse, Syracuse, New York

DELAYED GASTRIC EMPTYING is the most frequent immediate postoperative complication directly related to a gastroenteric anastomosis.[1] However, the definition of a postoperative delay in gastric emptying varies and thus the incidence also varies. Information about when patients are able to consume an adequate oral liquid intake after gastrojejunal anastomosis is difficult to find. In this study we examine this question and some factors that may predispose to a delay in gastric emptying.

Methods

The charts of all patients who underwent a gastrojejunal anastomosis with or without gastric resection or with or without vagotomy at the University Hospital of the SUNY Health Science Center at Syracuse and the Syracuse Veterans Administration Hospital were reviewed for the years 1979–1986. To qualify for analysis, the patients had to satisfy specific criteria. These include the absence of (1) carcinoma, perforation, peritonitis, or sepsis either before or after operation, (2) renal or respiratory or cardiac failure either before or after operation, (3) inflammatory bowel disease or insulin-dependent diabetes, (4) anastomotic leak and/or wound complications, (5) operative placement of either a prograde nasogastric or a retrograde jejunal tube *through* the anastomosis, (6) nonanastomotic bowel obstruction distal to the duodenum either before operation or in the immediate postoperative period, (7) emergent operation, (8) infection outside of the peritoneal cavity, and (9) hypokalemia. An additional criterion for inclusion into the study was access to an unrestricted intake of a liquid diet within 12 hours of passing flatus after operation. Forty-eight patients did not meet these criteria and were excluded from analysis unless stated specifically to the contrary. There was no operative mortality in patients who met the above criteria.

A data sheet was established before the study. The data sheet was designed to obtain specific information to answer specific questions to avoid random correlations that might appear as a result of statistical analyses. Information on the data sheets was entered into a data base computer file, the contents of which were rechecked against the original patient records to ensure accuracy. Three patient records did not contain the information required and were excluded from analysis.

Adequate oral liquid intake was prospectively defined as consumption of enough liquid to maintain a urinary output of greater than 480 ml/24 h for the rest of the patient's required hospitalization. However, three

Submitted for publication: July 20, 1987.

fourths of the patients were still receiving intravenous fluids when they started oral intake. If the intravenous fluids were continued for more than 24 hours for any reason after the start of what appeared to be an adequate oral intake, the patient was not included in the analysis. This criterion resulted in the exclusion of an additional 17 patient records. If a patient met the definition of adequate oral intake while still receiving intravenous fluids within 24 hours of starting oral fluids, the patient had to continue to meet the requisite urinary output after discontinuation of the intravenous line in order to continue to qualify for adequate intake. The requisite urinary output also had to be met when the patient was taking solid food, but no value was assigned to the adequacy of solid food intake.

Statistical analyses included frequency and independent t-test.

Results

Age, Sex, and Operation

The age of the patients ranged from 19 to 86 years with a mean (±SE) of 52.4 ± 1.9 years and a median and mode of 49 years. Forty-three patients were men and 42 were women. The various types of operations are shown in Table 1. There is a relatively large group of patients who underwent a gastrojejunostomy without an accompanying vagotomy. Eight patients in this group had prophylactic gastrojejunostomy done for what was erroneously diagnosed as carcinoma of the pancreas at the time of operation or duodenal obstruction due to chronic pancreatitis (these assessments are based on the subsequent clinical course extending 4–8 years after operation); three had duodenal obstruction related to prior operative trauma occurring at least 7.5 months previously; three had prior inadvertent vagotomy during operations for esophageal reflux at least 12 months previously; and three had prior vagotomy with a poorly functioning pyloroplasty performed at least 15 months previously.

Day of Liquid and Solid Intake

The mean postoperative day of starting an adequate oral liquid intake for the entire group of patients was 7.7 ± 0.9 and for solid intake it was 10.9 ± 1.1.

The cumulative frequencies of the postoperative days when liquid and solid intake were started and continued without difficulty are shown in Table 2. By the fourth postoperative day 29% of patients and by the seventh postoperative day 78% of patients were taking adequate liquids. In contrast, by the sixth postoperative day 28% of patients and by the eleventh day 78% of patients were taking solids. The mean difference in number of days between starting liquids and solids was 3.2 ± 0.4 and the difference was 3 days in 77% of the patients.

TABLE 1. *Operations Performed*

Type	*N*
Gastrojejunostomy	17
Vagotomy + gastrojejunostomy	16
Antrectomy	11
Vagotomy + antrectomy	26
Subtotal gastrectomy	15
Total	85

Obstruction Versus *No Obstruction*

The mean postoperative day of starting an adequate oral liquid intake for patients undergoing operation for obstruction was 6.5 ± 0.4 and for those without obstruction it was 8.3 ± 1.3. The mean difference is not significant.

The cumulative frequencies of the postoperative days when liquid and solid intake were started and continued without difficulty in patients with preoperative obstruction (28%) and no obstruction (78%) are shown in Tables 3 and 4. By the seventh postoperative day, an almost equal percentage of patients began a liquid diet (Table 3). By the ninth postoperative day, an almost equal percentage of patients began a solid diet (Table 4).

Vagotomy was performed in 11 of 24 patients with obstruction. There was no significant difference in terms

of the day liquids or solids were started in patients with or without vagotomy.

Vagotomy

A comparison of all patients who had a vagotomy was made with all but one patient who did not have a vagotomy. This patient did not start adequate oral intake until the 65th day after a gastrojejunostomy and was excluded from this analysis. Liquid intake was started on the fifth postoperative day (5.3 ± 2.1, N = 42) when vagotomy was not done. This is in contrast to the ninth mean postoperative day (8.8 ± 7.4, N = 42) when vagotomy was done. This 3.5-day difference in means is significant ($p < 0.004$).

* Z score = SD below or above mean.

Analysis by operative procedure is shown in Figure 1, which compares the cumulative frequencies of the various operations up to the 12th postoperative day. There is no significant difference between patients who had gastrojejunostomy alone, antrectomy alone, antrectomy with vagotomy, and subtotal gastrectomy. However, there is a significant difference between these groups of patients and those who had vagotomy with gastrojejunostomy ($p < 0.01$).

Because of the sharp difference observed for the day of starting adequate liquid oral intake after vagotomy with gastrojejunostomy, this procedure was compared with vagotomy with pyloroplasty (Heineke-Mikulicz) done during the same period of review and meeting the criteria listed in Methods (Fig. 2). By the seventh postoperative day, 92% of the patients who had vagotomy with pyloroplasty were taking adequate liquids orally in contrast to 56% of the patients who had vagotomy with gastrojejunostomy ($p = 0.02$). This difference did not appear to be attributable to variations in suture technique or use of an electrosurgical unit. The mean time for the start of an adequate liquid intake for patients who had vagotomy with pyloroplasty did not significantly differ from the operative procedures (other than vagotomy with gastrojejunostomy) listed in Table 1.

Antecolic Versus *Retrocolic Anastomosis*

Most of the anastomoses (76%) were done in a retrocolic fashion. All but four of the gastrojejunostomies without vagotomy (76.5% = 13 patients), all but one of the gastrojejunostomies with vagotomy (93.8% = 15 patients), all but eight of the antrectomies with vagotomy (69.2% = 18 patients), all but three of the antrectomies without vagotomy (72.7% = 8 patients), and all but four of the subtotal gastrectomies (73.3% = 11 patients) were performed in a retrocolic fashion. No significant difference for the group as a whole was apparent in comparing antecolic to retrocolic anastomoses. Significant differences also were not apparent by nonparametric analyses of the individual operative procedures.

Nasogastric Tube

A nasogastric tube was used after operation in 81.2% of the patients. Analysis of a 24-hour nasogastric tube output for each of the first three postoperative days showed no correlation with the time of starting adequate oral intake of liquids or solids. Furthermore, there was no correlation between the total or average nasogastric tube output and day of starting adequate oral liquids or solids. The average output for all patients was 397 ± 34 ml (mean ± SE, N = 68) for the first postoperative 24 hours, 541 ± 66 ml (N = 68) for the second 24 hours, and 403 ± 58 ml for the third 24 hours (N = 58). There were some significant differences in mean nasogastric outputs when comparing the various operative procedures. The mean output during the first postoperative day for patients who had gastrojejunostomy alone was significantly greater ($p < 0.05$) than the other operations. In addition there were some random significant differences in mean 24-hour outputs among the operative procedures on the second and third postoperative days.

No Nasogastric Tube

Only 16 patients did not have a nasogastric tube during their postoperative course. Ten of these patients began adequate oral intake by the end of day 5. The remaining six patients began adequate oral intake by days 6 to 12.

Electrosurgical Unit

Only 34% of the patients had their gastroenterostomy stomas fashioned exclusively using an electrosurgical unit. This did not significantly affect the day of starting liquid or solid food.

Suture Versus *Staples*

Suture alone was used to construct the anastomosis in 96.5% of patients. Two layers of sutures were used in 65.9% of these patients. No significant difference was apparent between the use of a one- or two-layered anastomosis.

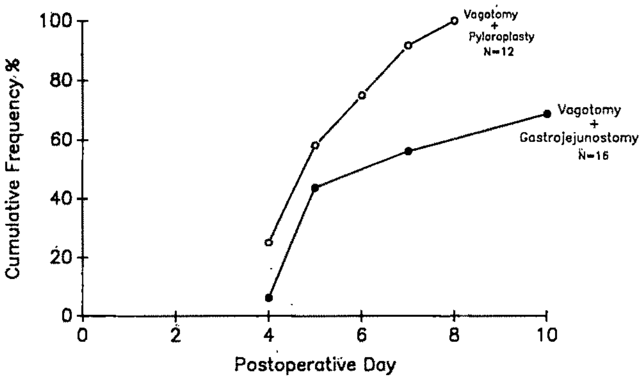

FIG. 2. Cumulative frequencies of postoperative day of starting adequate liquid oral intake after the vagotomy with gastrojejunostomy and vagotomy with pyloroplasty.

A valid comparison between sutures and staples cannot be made. Nevertheless, the three patients who had a stapled anastomosis began adequate liquids on days 4, 8, and 11 and solids on days 9, 11, and 14, respectively.

Surgeon

No analysis of individual surgeons was made because of the varible number of involved operative teams.

Reoperation

Eight patients had reoperation and were not included in any of the above analyses. Two reoperations were for small bowel obstruction occurring on postoperative days 18 and 35. Both patients were discharged from the hospital eating a regular diet before being readmitted for the obstruction. Three patients who had gastrojejunostomy alone had reoperation because of failure of gastric emptying on postoperative days 10, 14, and 28. Three patients who underwent antrectomy with vagotomy had reoperation because of failure of gastric emptying on postoperative days 10, 14, and 60. Upper gastrointestinal radiographs showed virtually no emptying in four patients and two showed minimal emptying. In all six of these patients, however, there was evidence of edema at the anastomosis. At reoperation, an instrument or finger passed through the anastomosis, indicating that it had not strictured to the point of closure, and no obvious technical errors from the original operation were evident. All patients undergoing reoperation consumed an adequate liquid diet by the eighth postoperative day (days 3, 4, 4, 5, 5, 8). Further analysis of the six patients who had reoperation because of failure of emptying was not carried out because of their small number and the arbitrary, variable criteria used for the timing of reoperation.

Discussion

The definition of delayed gastric emptying beginning in the immediate postoperative period of a gastrojejunostomy varies. It ranges from inability to tolerate oral intake by 48 hours,[2,3] or by 5 or 8 days[4–6] to 10 days after operation[7–9] or inability to tolerate solid food for more than 14 days after operation.[10] Others use the requirement of a nasogastric tube for more than 3[11] or 10[12] days after operation. Delayed emptying that persists for less than 3 weeks has been considered to be a milder form of the problem.[13] Few if any define what is meant by tolerating oral intake. The incidence of delayed gastric emptying after gastrojejunostomy also varies[1–3,5,11] because of the spectrum of definitions. Thus, the incidence ranges from 0 to 20%.[2,9,11]

The current study involves otherwise healthy patients and defines an adequate oral intake as that which is sufficient to prevent oliguria. Inability to do so constitutes a reasonable clinical definition of delayed gastric emptying when it is associated with nausea, vomiting, or a sensation of epigastric fullness that prevents further oral intake. The mean time by which all patients undergoing a gastrojejunal anastomosis with or without gastric resection or vagotomy can consume an adequate oral intake is 8 days. However, 84% of the patients could swallow an adequate liquid intake by this time. Only 8% of patients had sufficient oral intake of liquid by the third postoperative day, but this figure increased to 55% by the fifth day and to 91% by the eleventh day. Solid food was tolerated on the average 3 days after the start of an adequate oral liquid intake.

Multiple reasons have been proposed to explain why gastric emptying may be delayed after gastroenteric anastomoses. Several of the causes are either speculative or anecdotal. Explanations include edema, hematoma, anastomotic leak, ileus resulting from intra- or extra-abdominal infection, starch peritonitis, adhesions, potassium deficiency, pancreatitis, too small a stoma, inadvertent suture of anterior to posterior walls of anastomosis, too much inversion of tissue at the anastomosis, scarred (unsuitable) bowel used for anastomosis, mesocolic compression, retroanastomotic hernia, jejunogastric intussusception, marginal ulceration, kinking of the efferent loop, prolapse of mucosa through the anastomosis, nondependent anastomosis, malalignment of the anastomosis, and colonic distention compressing an antecolic gastrojejunostomy. Other proposed causes include chronic preoperative obstruction, inanition, gastritis, a blind loop, too large an anastomosis, food bolus impaction, two-layer as opposed to one-layer anastomosis, an improperly placed stoma, too long or too short a jejunal loop, narcotic medication, the efferent loop situated higher than the afferent loop, the direction of peristalsis in the efferent loop not corresponding to normal direction of emptying by the stomach, autonomic nerve dysfunction or gastric atony, and experience of the surgeon.[3,6,11,14,15] About the only technical issue that there appears to be some agreement on is the lack of apparent relationship between delayed emptying and an antecolic or a retrocolic gastrojejunal anastomosis.[4] [16]

Often no predisposing factors are identified[1] and the cause of postoperative gastric retention frequently is not found at reoperation. This suggests that many of the anatomic and some of the functional causes are preventable. Thus, it appears that transient functional and/or anatomic changes account for delayed emptying in the majority of instances. The observation that most patients progress to an adequate oral intake with conservative management support these interpretations.

Edematous swelling is probably the most common cause of early postoperative stenosis of the stoma.[17] In contrast, others have reasoned that mechanical causes should produce obstruction equally as often in the afferent stomal inlet as in the efferent outlet; however, afferent inlet dysfunction is unusual.[18] However, afferent limb peristalsis might overcome any edema at the anastomotic site. Such edema most often is not related to plasma colloidal oncotic pressure. No relationship was found in one study between delayed gastric emptying and postoperative serum protein values or colloidal osmotic pressure.[19] Although extreme forms of hypoproteinemia may be associated with anastomotic edema, such hypoproteinemia is rarely seen in patients undergoing operation. Use of an electrosurgical unit to divide the stomach and jejunum might be expected to cause greater edema, but our data do not support the contention that such a unit contributes to delayed emptying. What is interpreted as anastomotic edema is seen on virtually every upper gastrointestinal radiograph obtained in the immediate postoperative period. However, it is difficult to correlate the degree of apparent edema with delayed emptying of radiographic contrast material.

It is also difficult to distinguish by radiography between anastomotic edema and submucosal hemorrhage. Submucosal hemorrhage at the site of anastomosis can contribute to stomal obstruction, but there are no substantive data indicating how long a hematoma contributes to the problem. The opinion has been expressed that submucosal hemorrhage at the site of the anastomosis usually subsides within 10 days.[20] In contrast, obstruction from a spontaneous hematoma of the jejunum in a patient receiving warfarin is known to usually subside within 48–72 hours.[21] Experimentally, however, anastomotic hematoma or edema generally subsides by the 29th postoperative day.[22]

Few, if any, would argue that gentle handling of tissue is essential to minimize the degree of anastomotic edema. While roughness contributes, delayed gastric emptying frequently cannot be explained on the basis of trauma alone. No matter how gently the stomach is handled, a problem with emptying may still occur[23] in the absence of an obvious technical error. Delicate partition alone of the bowel can result in edema, as is often seen after division of a transverse colostomy.

Some believe that atony of the gastric remnant as a result of vagotomy is a common cause of delayed emptying. This explanation is based on the frequent observation that radiographic contrast or an endoscope or, at reoperation, an instrument or finger can be passed through the anastomosis. Although these maneuvers may be reassuring that no gross technical error was made to account for delayed emptying, they do not help to quantitate the degree of resistance (for example, from edema) offered by the anastomosis. Gastric atony has even been invoked as a cause of efferent stomal dysfunction in patients who have subtotal gastrectomy *without vagotomy.*[18] Others, however, believe that atony of the gastric remnant is rare.[24] The notion of atony associated with vagotomy is not in keeping with a currently accepted physiologic concept that parasympathetic denervation of the fundus and antrum cause a loss of receptive relaxation of the stomach and thus faster emptying of liquid. Furthermore, postoperative gastric atony may be euphemistic, as an atonic stomach with a patent outlet should empty by gravity. If this is the case, even "mild" anastomotic edema may play an important role in delayed emptying. The concept of atony also does not account for the fact that a prolonged period of delayed emptying is frequently overcome by redoing the gastroenteric anastomosis in this circumstance. On the other hand, impaired tone of the residual gastric pouch has been described after gastrectomy with vagotomy beyond the immediate postoperative period,[25] but the prevalence and significance of this finding is still unclear.

One study suggests that gastric tone, jejunal peristalsis, changes in intra-abdominal pressure, diaphragmatic motion, and gravity are probably the primary factors in emptying the gastric remnant.[26] Gastric evacuation requires a pressure gradient from stomach to intestine, but the significance of gravity or respiratory movements has been questioned.[27] However, prolonged gastric emptying of barium (at least twice as long) was observed in the head down compared to the upright position in 80% of patients after subtotal gastrectomy without vagotomy.[26] It is not difficult to imagine that in the presence of a certain degree of anastomotic edema, the pressure gradient might be insufficient for drainage to occur by gravity.

No significant differences were observed in the current study for the time it took patients to consume an adequate oral liquid intake after gastrojejunostomy or subtotal gastrectomy without vagotomy or vagotomy with antrectomy. In contrast, it took significantly longer for patients who underwent vagotomy with gastrojejunostomy to consume an adequate oral intake; this was particularly noticeable after the fifth postoperative day (Fig. 1). At least 77% of the former group of patients consumed an adequate intake by the seventh postoperative day, which is in contrast to 56% of the patients who had a gastrojejunostomy with vagotomy. This observation could be due either to a speculative perturbation resulting from vagotomy or a type II statistical error, which is also a problem with other studies reporting some or no differences between various types of operations.[2,9,12,13,28] These studies are difficult to compare because of the lack of reasonably precise definitions of adequacy of oral intake and variable technical, operative details.

The current data suggest that vagotomy *per se* does not account for the apparent delay in consumption of an adequate oral liquid intake. If vagotomy alone were important, one would expect delayed emptying also to occur after vagotomy with pyloroplasty and vagotomy with antrectomy. This was not observed in the current study. Similar reasoning also suggests that gastroenterostomy alone also does not account for delayed emptying. Motor incoördination of the efferent loop might increase resistance to gastric outflow,[29] but the prevalence and significance of this possibility in the immediate postoperative period is unclear.

Some believe that longstanding gastric outlet obstruction is a predisposing cause of delayed gastric emptying.[6,30] The usual explanation is that obstruction leads to a loss of gastric tone. It has been suggested that subtotal gastrectomy is associated with a lower incidence of delayed gastric emptying than vagotomy with drainage done for obstructing ulcer disease.[7] The current study suggests that gastroenterostomy with or without vagotomy is not associated with prolonged emptying in the presence of obstruction. Vagotomy with gastroenterostomy is a very satisfactory long-term procedure for obstruction.[31,32]

Whatever the causes of delayed emptying may be, it is difficult to distinguish the basis of obstruction by radiographic[8] and/or endoscopic means. Some degree of anastomotic narrowing was seen in all of our patients who had gastrointestinal radiographs in the immediate postoperative period. Anastomotic edema is also observed after low anterior resection of the rectum,[33] but clinically significant "outlet obstruction" is unusual following this procedure. However, an important difference between intestinal and gastroenteric anastomoses is that the former have different proximal peristaltic properties than the residual stomach anastomosed to the proximal jejunum.

The number of confounding variables involved in a patient's ability to consume an adequate oral intake of liquids or solids after operation makes it exceedingly difficult to identify those aspects that are significant. This is further compounded by the observations that gastric emptying judged to be normal or abnormal by barium flowing through a gastrojejunal anastomosis or more objective studies such as kinetic analyses of isotopic rates of gastric emptying do not necessarily correlate with adequacy of postoperative oral intake and maintenance of normal hydration or even nutrition.

Once cefoxitin was the only single agent you had for prophylaxis and treatment of mixed abdominal and pelvic infections. Now it's being steadily replaced in hospitals by something better...CEFOTAN. Here's why.

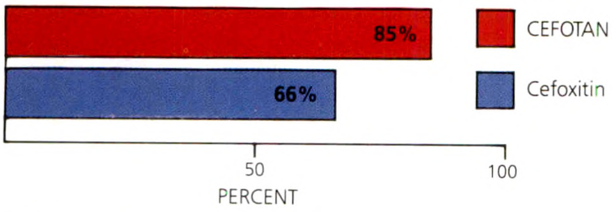
Superior activity.

CEFOTAN is 8 to 16 times more active than cefoxitin against the most commonly isolated gram-negative aerobes—*Escherichia coli, Klebsiella pneumoniae,* and *Proteus mirabilis.**[1] What's more, CEFOTAN possesses activity against *Enterobacter* sp[2]...often resistant to cefoxitin.

CEFOTAN is also as active as cefoxitin against *Bacteroides fragilis.**[3-6] Recent studies involving 8 US medical centers, however, found more *B fragilis* isolates susceptible to CEFOTAN than to cefoxitin.[7]

*In vitro activity does not necessarily correlate with in vivo effectiveness.

Susceptibility† of *B fragilis,* CEFOTAN vs cefoxitin[7]



†FDA-recommended susceptible MIC breakpoints for both are $\leq 16\ \mu g/mL$.

Longer duration of action... more convenient dosing.

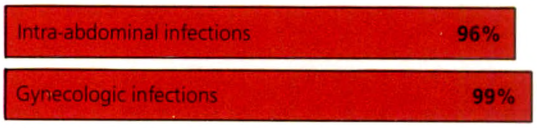
In comparative studies CEFOTAN provided antimicrobial activity against susceptible pathogens for a full 12 hours, while cefoxitin provided coverage for less than 6 hours.[8-9] As a result, only a single dose of CEFOTAN is required for surgical prophylaxis, compared with the three-dose regimen of cefoxitin—improving patient comfort and reducing hospital costs.

Please see next page for brief summary of prescribing information.

Exceptional clinical success rates.

The twice-daily therapeutic dose of CEFOTAN demonstrated excellent clinical success rates,‡ as you can see below.

Clinical success rates‡[10]



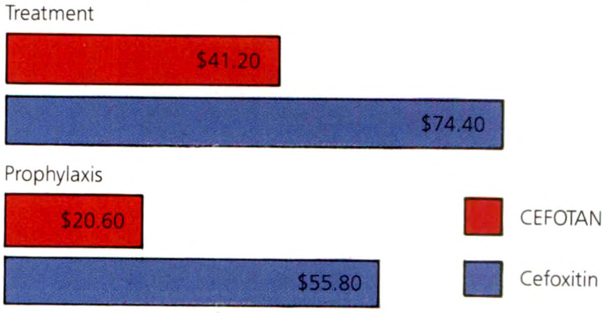
‡Clinical success is defined as complete clearing or substantial improvement in signs and symptoms of infection.

CEFOTAN is indicated for the treatment of intra-abdominal and gynecologic infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis, B bivius,* and *B disiens,* but not *B distasonis, B ovatus,* or *B thetaiotaomicron.*

Cost savings without compromise.

Treatment with CEFOTAN can save your hospital 45% in total costs for therapy when compared with cefoxitin, and 63% for surgical prophylaxis. Furthermore, CEFOTAN is well tolerated, with the safety profile you've come to expect from cephalosporins.[10]

Cost per day,§ CEFOTAN vs cefoxitin



§Based on overall antibiotic acquisition, preparation, and delivery[11] costs for comparable regimens: Treatment—CEFOTAN, 2 g × 2; cefoxitin,[12] 2 g × 4. Prophylaxis—CEFOTAN, 2 g × 1; cefoxitin,[12] 2 g × 3.

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin.

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

† Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired

CEFOTAN® (cefotetan disodium)

fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

Orthotopic Liver Transplantation for Primary Sclerosing Cholangitis

J. WALLIS MARSH, JR., M.D., SHUNZABURO IWATSUKI, M.D., LEONARD MAKOWKA, M.D., PH.D., CARLOS O. ESQUIVEL, M.D., PH.D., ROBERT D. GORDON, M.D., SATORU TODO, M.D., ANDREAS TZAKIS, M.D., CHARLES MILLER, M.D., DAVID VAN THIEL, M.D., and THOMAS E. STARZL, M.D., PH.D.

The incidence or diagnostic rate of sclerosing cholangitis is increasing. Because of the lack of effective medical or surgical therapy for patients with end-stage liver disease and sclerosing cholangitis, results with orthotopic liver transplantation were examined. The results of 55 consecutive liver replacements for this disease were reviewed. The 1- and 2-year actuarial survival rates are 71% and 57%, respectively. Orthotopic liver transplantation for end-stage liver disease from sclerosing cholangitis has emerged as the most effective therapy.

From the Department of Surgery, University Health Center of Pittsburgh, University of Pittsburgh, and the Veterans Administration Medical Center, Pittsburgh, Pennsylvania

SCLEROSING CHOLANGITIS is an enigmatic disease usually found in men younger than 50 years and, more often than not, is associated with inflammatory bowel disease, particularly ulcerative colitis. The treatment modalities used for this disease have been as varied as the descriptions of the disease itself and illustrate the dissatisfaction with the currently available medical/surgical therapies. Although the histologic course of sclerosing cholangitis is considered benign, the disease most often takes an indolently malignant course and is, in fact, a pernicious disease. Importantly, there is an apparent increasing incidence, or at least an increasing diagnostic rate, of the disease in most developed countries.

We report our experience with hepatic replacement in 55 patients who had primary sclerosing cholangitis as the indication for liver transplantation. We have tried (1) to determine the applicability, success rate, and survival of orthotopic liver transplantation for patients with primary sclerosing cholangitis, (2) to determine the recurrence rate of sclerosing cholangitis, should it occur, and (3) to assess the course of the associated inflammatory bowel disease under immunosuppression after liver transplantation.

Case Material and Methods

Between January 1, 1980, and June 30, 1986, 604 primary orthotopic liver transplants were performed at the University of Colorado Health Science Center (through 1980), the University Health Center of Pittsburgh (since 1981), and the Pittsburgh-affiliated Baylor University Medical Center at Dallas (since 1985). All patients were treated with combination prednisone–cyclosporine therapy as has been described elsewhere.[1-3] Patients were considered to have "primary" sclerosing cholangitis[4-7] when there were (1) typical cholangiographic findings of the disease, (2) pathologic confirmation of the disease from the total hepatectomy specimen, and (3) the absence of a history or pathologic evidence consistent with secondary biliary cirrhosis from other causes.

Fifty-five patients received orthotopic liver transplantation for end-stage primary sclerosing cholangitis. Thirty-five were male (63.6%) and twenty were female (36.4%). Their ages ranged from 15 to 58 years with a median age of 36 years. Only four patients were older than 50 years.

The indications for transplantation were persistent or recurrent variceal bleeding in 27.2% (15 of 55 patients),

Partial or total abdominal colectomy	4
Proctocolectomy with ileostomy	3
Small bowel resection (Crohn's disease)	1

ascending cholangitis in 27.2% (15 of 55 patients), or hepatic decompensation, including encephalopathy, coagulopathy, anorexia, ascites, fatigue, pruritus, and/or 3–4+ varices, in 45.5% (25 of 55 patients). Because of the risk of cholangiocarcinoma, the timing of transplantation cannot be accurately defined. In general, however, transplantation is encouraged when the bilirubin level exceeds 10 mg/dl or is rapidly rising, when the patient's lifestyle has begun to significantly deteriorate, or with any suspicion of cholangiocarcinoma.

Thirty-six (65.4%) of 55 patients had a history of inflammatory bowel disease. Thirty-two patients had ulcerative colitis, and four patients had Crohn's disease. Cholangiocarcinoma was found in the hepatectomy specimen of five patients (9%). Three of 55 patients had had a carcinoma of the right colon removed by radical right colectomy, 11, 4, and 4 years, respectively, before liver transplantation without evidence of recurrence.

Thirty-one (56.3%) of 55 patients had undergone prior biliary tract surgery for diagnosis or treatment of the sclerosing cholangitis (Table 1). Fifteen patients had undergone hepaticojejunostomy, six had cholecystectomy alone, five had T-tube drainage of the choledochus, three had cholecystectomy and percutaneous choledochal drainage, one had choledochoduodenostomy, and one had cholecystojejunostomy.

Eight patients (14.5%) had undergone prior bowel surgery for either inflammatory bowel disease or for complicating carcinoma. Three patients had undergone partial or total abdominal colectomy. Two of the three patients had proctocolectomy with ileostomy, and one patient had proctocolectomy with an ileoanal pullthrough. A fourth patient had undergone a small bowel resection for Crohn's disease.

The liver disease was diagnosed 1–16 years (mean: 5.8 years) before transplantation, and the bowel disease, when present, had existed from 2 to 29 years (mean: 14.8 years). In all but five of the 36 cases with coexisting inflammatory bowel disease, the bowel disease preceded the sclerosing cholangitis.

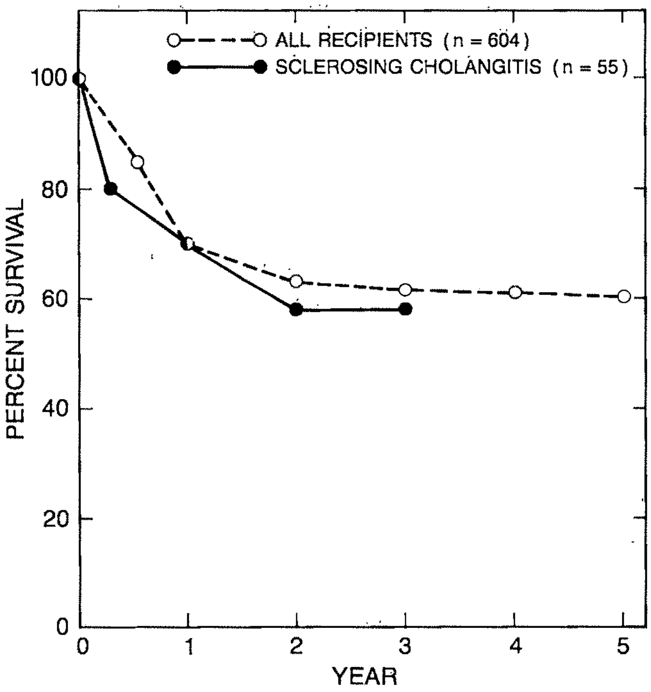

FIG. 1. Actuarial survival after orthotopic liver transplantation.

Results

Survival

As of September 1, 1986, there were 37 patients living (67%) and 18 dead (33%) with a mean follow-up period of 19 months (range: 4–46 months). The actuarial survival rates at 3, 6, 9, 12, 24, and 36 months were 80%, 76%, 76%, 71%, 57%, and 57%, respectively, calculated by the life table analysis of Kaplan-Meier. (Fig. 1). The longest surviving patient who had transplantation for primary sclerosing cholangitis has been observed for 46 months.

Cause of Death

Eleven patients died within 3 months of transplantation, all from direct complications of transplantation or the associated immunosuppression. Technical failures, primary nonfunction of the graft, infectious complications, and irreversible acute rejection were the leading causes of death. Two patients died between 3 and 6 months, one of graft failure and sepsis, and another of biliary sepsis due to recurrence of cholangiocarcinoma. Between 6 and 12 months one patient died of an unrecognized lymphoproliferative disorder. Three patients

TABLE 2. *Causes of Death after Orthotopic Liver Transplantation*

Time of Death after Transplant	No. of Deaths	Cause of Death	
0–3 months	11 patients (19 transplants)	Nine deaths related directly to graft failure: cause of graft failure (including retransplantation)	
		primary nonfunction	7
		technical failure	3
		acute rejection	4
		Two deaths related to immunosupression	
		intra-abdominal abscess	1
		cryptococcal meningitis	1
3–6 months	1 patient	Graft failure and sepsis	
	1 patient	Biliary sepsis and recurrent cholangiocarcinoma	
6–12 months	1 patient	Unrecognized lymphoproliferative disorder	
1–2 years	1 patient	Recurrent cholangiocarcinoma	
	1 patient	Systemic fungal infection	
	1 patient	GI bleeding and liver failure from portal vein thrombosis	
2–3 years	No deaths		
>3 years	1 patient	Chronic rejection	

died between 1 and 2 years, one of recurrent cholangiocarcinoma, one of systemic fungal infection, and the other of gastrointestinal bleeding and liver failure due to rethrombosis of the portal and superior mesenteric veins which had been opened with thrombophlebectomy at the time of transplantation. No patient died between 2 and 3 years after transplantation. One patient died of liver failure due to chronic rejection more than 3 years after transplantation (Table 2).

Unrecognized Cholangiocarcinoma

Previously unrecognized cholangiocarcinoma was found in the surgical specimen of five of the 55 patients. There were three women and two men with an average age of 35.4 years (range: 24–37 years). Two patients had no history of inflammatory bowel disease; three had had ulcerative colitis for 16, 20, and 29 years. The patient who had had ulcerative colitis for 16 years had undergone a right colectomy 4 years before liver transplantation for a Duke's B carcinoma of the colon with no evidence of recurrence. The clinically evident liver disease in this subset of patients had been present 1, 2, 4, 7, and 14 years, clearly illustrating that longstanding liver disease is not a prerequisite for the development of cholangiocarcinoma. Two of these patients died as a result of recurrent cholangiocarcinoma 4 and 12 months after transplantation. Three patients are alive, but the follow-up period is short. The first patient still living is 1 year post-transplantation, received adjunctive chemotherapy and radiotherapy, but has recurrence of disease. The remaining two patients are 3 months post-transplant without evidence of recurrence: both have undergone radiotherapy and one will undergo chemotherapy as well.

Inflammatory Bowel Disease after Liver Transplantation

During the observation period of 4 months to 4 years, nine (34.5%) of 26 patients who had had inflammatory bowel disease before transplantation and who survived more than 3 months after transplantation developed reactivation or exacerbation of the bowel disease. However, the recurrent inflammatory bowel disease was minimally symptomatic in seven of the nine patients, requiring only short-term treatment with sulfasalazine, and was moderate in two of nine patients, requiring long-term sulfasalazine therapy and increased doses of steroids.

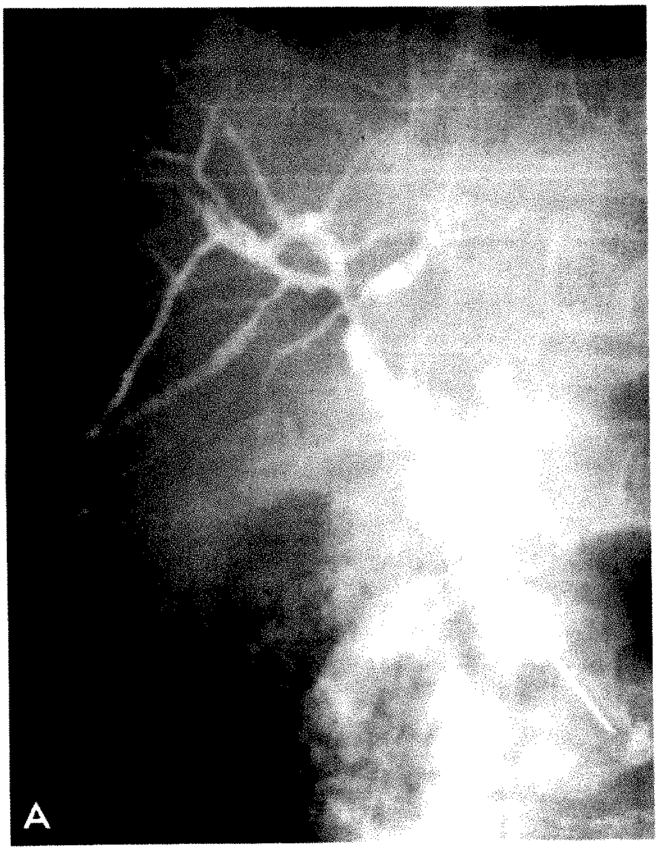
Annual or semiannual colonoscopic examinations of the surviving patients have not detected any colorectal malignancy during this relatively short period of observation, but in none of the patients with pre-existing abnormalities have the colonoscopic findings become totally normal. It is also noteworthy that none of the patients without a pre-existing history of inflammatory bowel disease has developed it after transplantation.

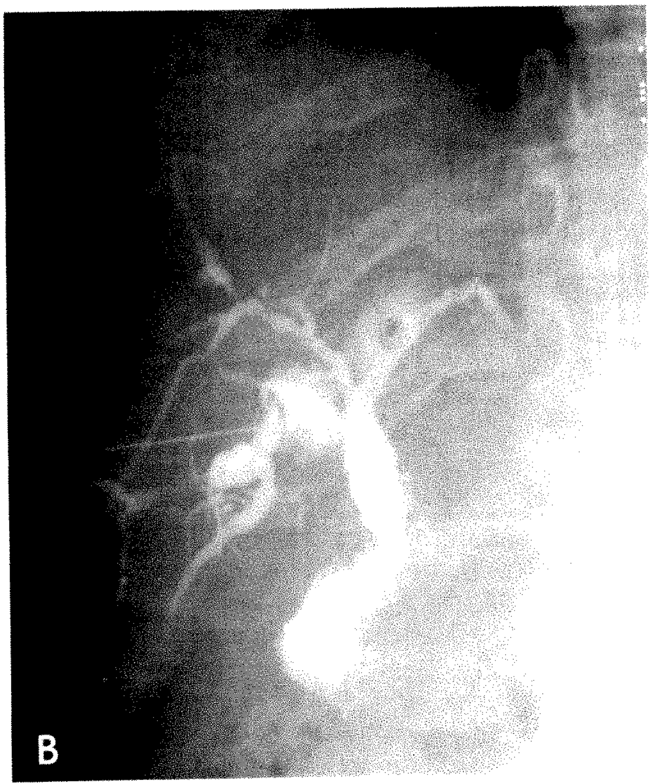
Recurrence of Sclerosing Cholangitis

In one patient, chemical and radiological abnormalities developed in the graft compatible with sclerosing cholangitis 1 year after transplantation (Fig. 2A), but the abnormalities have been stable for the ensuing year. Four patients whose original liver disease was not sclerosing cholangitis also had similar abnormalities develop after histologically proven graft rejection (Fig. 2B).

Discussion

Primary sclerosing cholangitis remains a disease of unknown cause. It has become the third most common





FIGS. 2A and B. *A*. Cholangiogram showing changes of sclerosing cholangitis 1 year after transplantation. The original diagnosis was sclerosing cholangitis. *B*. Cholangiogram showing changes of sclerosing cholangitis in a patient with a >90% stenosis of the hepatic artery and after multiple biopsy-proven rejections. The original diagnosis was chronic active non-A, non-B hepatitis.

indication for orthotopic liver transplantation in adults, the first being postnecrotic cirrhosis and the second being primary biliary cirrhosis. Treatment has been attempted with steroids, cholestyramine, azathioprine, D-penicillamine,[8] choledochoenteric anastomoses,[9] and choledochal drainage by T-tube or Silastic® transhepatic stents.[10]

Wiesner and LaRusso,[11] have reported the largest group of patients with primary sclerosing cholangitis treated without transplantation at a single institution. Thirty-nine (78%) of their 50 patients had adequate follow-up for presentation. Thirteen (33%) of the 39 patients were dead after a mean interval of 57 months after diagnosis. At the time of reporting, 26 patients (66%) were alive, but 12 had end-stage liver disease. Thus, an unsatisfactory result had been obtained in at least 64% of the cases.

Cameron et al.,[10] have reported the operative placement of Silastic transhepatic stents in a group of 11 patients. Eleven of the original 22 patients were not selected for operation, and of those operated on the majority have either died or come to transplantation, including three patients treated by us. The prior performance of this type of operation has made transplantation exceptionally difficult.

The fact that a satisfactory result could be obtained in two thirds of the 55 patients herein reported after a mean follow-up of more than 1.5 years is encouraging. All patients were medical/surgical treatment failures with liver disease that preceded the transplantation by a mean of 68 months. Even though 14 patients died in less than 1 year, the 71% actuarial 1-year survival and the 57% 2-year survival rates are not significantly different than that of the overall group of 604 patients of our total series.

Cholangiocarcinoma was found at pathologic examination of the removed liver specimen in five (9.9%) of 55 patients. Two of these recipients have died and one has recurrence of disease. Although two patients are still disease free, their long-term outlook remains to be determined since the follow-up period has been short. We currently believe that any patient undergoing stenting of the biliary tree should have brushings, cytologic examination, and/or needle biopsies obtained in an attempt to bring these patients to earlier transplantation before malignant changes occur.

This experience demonstrates the effectiveness of orthotopic liver transplantation for patients with advanced primary sclerosing cholangitis. In the future, liver replacement should not be reserved as a last minute operation for moribund patients who have undergone the gamut of palliative medical and surgical therapies that have not been shown to be effective in prolonging life or reducing morbidity. Specifically, palliative operations such as choledochoenterostomy for sclerosing cholangitis should be avoided since the same results can be obtained by transhepatic biliary drainage and balloon dilatation or by endoscopic procedures, particularly in those patients whose sclerosing cholangitis is limited to a narrow segment of the extrahepatic biliary tree. With a 2-year survival rate of 57%, orthotopic liver transplantation has emerged as the sole form of therapy that offers patients who had failed treatment a chance at returning to normalcy at the cost of the least number of lives.

Partial Biliary Obstruction Caused by Chronic Pancreatitis

An Appraisal of Indications for Surgical Biliary Drainage

THOMAS J. STAHL, M.D., MELODY O'CONNOR ALLEN, M.D., F.A.C.S., HOWARD J. ANSEL, M.D.,
and JACK A. VENNES, M.D.

From the Departments of Surgery, Radiology, and Gastroenterology, the University of Minnesota and Veterans Administration Medical Center, Minneapolis, Minnesota

This paper presents a retrospective review of 38 patients with intrapancreatic bile duct strictures secondary to chronic alcoholic pancreatitis. The strictures were identified by endoscopic retrograde cholangiopancreatography (ERCP). All patients with pancreatic cancer and gallstone pancreatitis were excluded. The mean alkaline phosphatase and total bilirubin values were 344 ± 57 IU/dl and 4.4 ± 0.7 mg/dl, respectively. The mean stricture length was 3.9 ± 0.5 cm, and the mean common bile duct (CBD) diameter was 1.8 ± 0.2 cm. The degree of bilirubin and alkaline phosphatase elevation did not correlate with stricture length or the severity of bile duct dilatation. Eighteen of the 38 patients received surgical biliary drainage (BD) as part of their initial therapy, and 20 patients did not. Liver function tests, intrapancreatic stricture length, and the degree of proximal CBD dilation were comparable in these two groups. Patients not undergoing BD did well clinically as only one patient required BD over an average follow-up period of 3.8 years. In conclusion, bypass of these strictures is usually unnecessary, and most patients may be safely treated without operation.

INTRAPANCREATIC BILIARY STRICTURES have been estimated to occur in from 3 to 29% of patients with chronic alcoholic pancreatitis.[1-3] Opinions regarding the clinical significance and appropriate treatment for these lesions are variable. Strictures are often suspected in patients with clinical and laboratory signs of biliary stasis in conjunction with an acute exacerbation of chronic pancreatitis. Operative biliary drainage has often been recommended to prevent both the acute development of cholangitis and late development of biliary cirrhosis.[4,5] The low incidence of cholangitis and biliary cirrhosis in association with biliary strictures has prompted others to advocate a less aggressive approach to the care of these patients.[3,6-8] Since all prior published reports of patients with biliary strictures due to benign pancreatic disease report results of operative therapy, little is known about the natural history of patients who are not operated on. This study summarizes the clinical course of 38 patients with biliary strictures and chronic pancreatitis in an attempt to compare the risks and benefits of nonoperative therapy (20 patients) with those of traditional operative drainage of the biliary tree (18 patients).

Patients and Methods

Endoscopic retrograde cholangiopancreatography (ERCP) records from the Minneapolis Veterans Administration Hospital were reviewed from 1973 to 1985. All patients with clinical and radiologic evidence of chronic pancreatitis who were found to have an ERCP-proven stricture of their intrapancreatic common bile duct (CBD) were included in this study. Inpatient and outpatient medical records of each patient were reviewed. The ERCPs were interpreted by a single staff radiologist (H.A.). Patients with either choledocholithiasis or pancreatic cancer as the possible cause of ductal abnormalities were excluded.

All results are presented as mean ± SEM. Student's t-test and correlation coefficients were used for statistical comparison. A p value <0.05 was considered significant.[9]

Results

Clinical Features

The mean age of the 38 patients was 49.5 years with a range from 23 to 66 years. Thirty-seven of the 38 patients were men. All patients had a long history of alcohol abuse, with over 60% having had one or more previous episodes of acute pancreatitis. The presenting signs and symptoms were abdominal pain (92%), weight loss (34%), jaundice (29%), nausea (24%), emesis (16%), fatigue (11%), gastrointestinal bleeding (8%), anorexia, fever, and ascites (3%).

Laboratory Values

The serum alkaline phosphatase was the laboratory test most frequently elevated at the time of admission (63% of patients) with an average value of 344 ± 57 IU/dl (normal range: 21–91 IU/dl). The total serum bilirubin level was elevated in 50% of patients, with an average value of 4.4 ± 0.7 mg% (normal range: 0.3–1.0 mg%). The SGOT was elevated in 54% of patients.

ERCP Findings

The intrapancreatic portion of the common bile duct (CBD) was strictured on ERCP in all patients. The mean length of the strictures was 3.9 ± 0.5 cm. The CBD proximal to the stricture was dilated in 64% of patients, with an average duct diameter of 1.8 ± 0.2 cm (normal diameter <1.0 cm), and a range from less than 1.0 to 4.0 cm. The configuration of the CBD was variable, as seen in Figures 1–4. The pancreatic ductal system routinely revealed a wide range of changes consistent with chronic pancreatitis. Findings varied from early side branch blunting to dilatation, tortuosity, and segmental stenosis of the main pancreatic duct. Pseudocysts were demonstrated in the pancreas in 18 of 38 patients (47%).

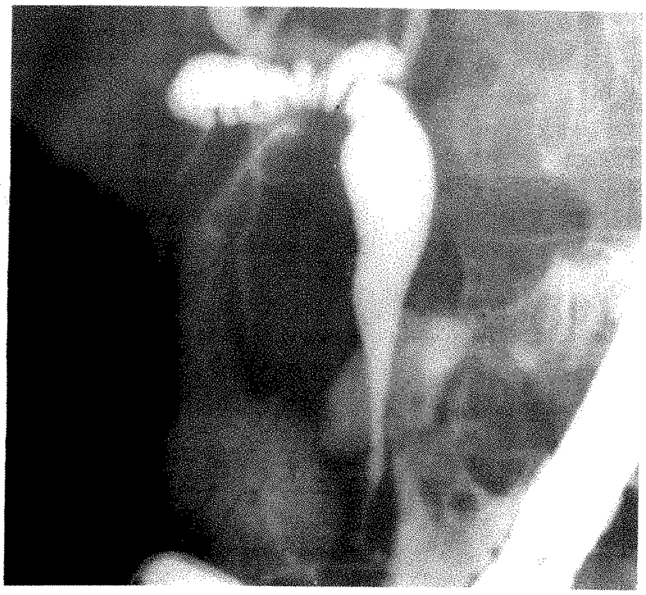

FIG. 1. A 48-year-old white man had pain and jaundice. Admission laboratory values were alkaline phosphatase of 750 IU/L and total bilirubin of 8.1 mg/dl. A 7.0-cm biliary stricture with a 1.4-cm diameter proximal CBD is seen on this cholangiogram. This patient was treated successfully with conservative medical therapy.

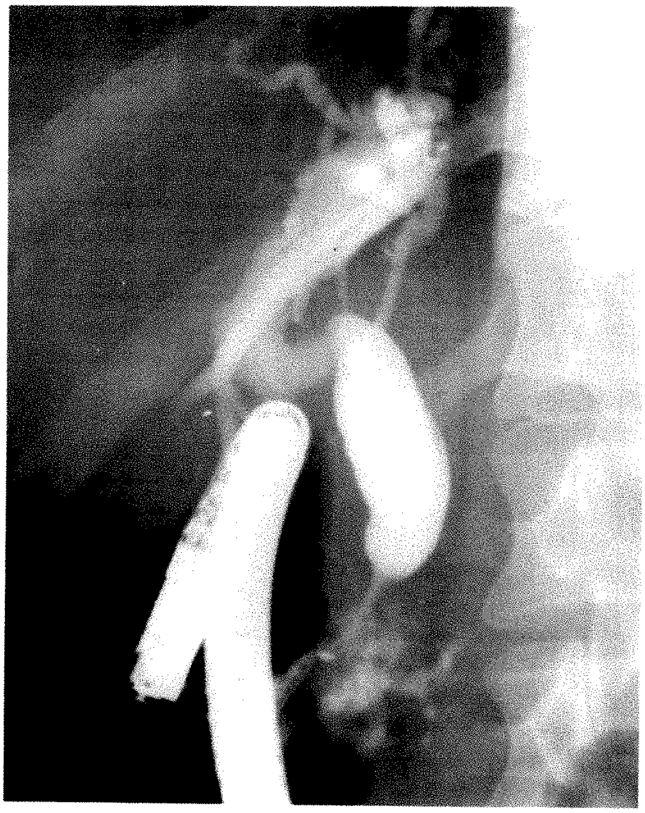

FIG. 2. A 36-year-old white man had recurrent pain and jaundice. Admission alkaline phosphatase level was 395 IU/L and total bilirubin level was 10.0 mg/dl. A 2.8-cm biliary stricture with 1.3-cm diameter proximal CBD was seen on this cholangiogram. This stricture was treated by choledochoduodenostomy. Follow-up for 1 year revealed no further problems.

Therapy

The various treatments the 38 patients received are depicted in Figure 5. In 18 patients, surgical biliary drainage (BD) was part of the initial therapy, whereas the remaining 20 patients did not have BD. Of the 18 patients who had BD, 13 had a bilioenteric anastomosis, and five had T-tube drainage of the common bile duct. Of the 20 patients who did not have BD, 15 had other surgical procedures performed, and five were treated strictly with nonsurgical measures. Concomitant pan-

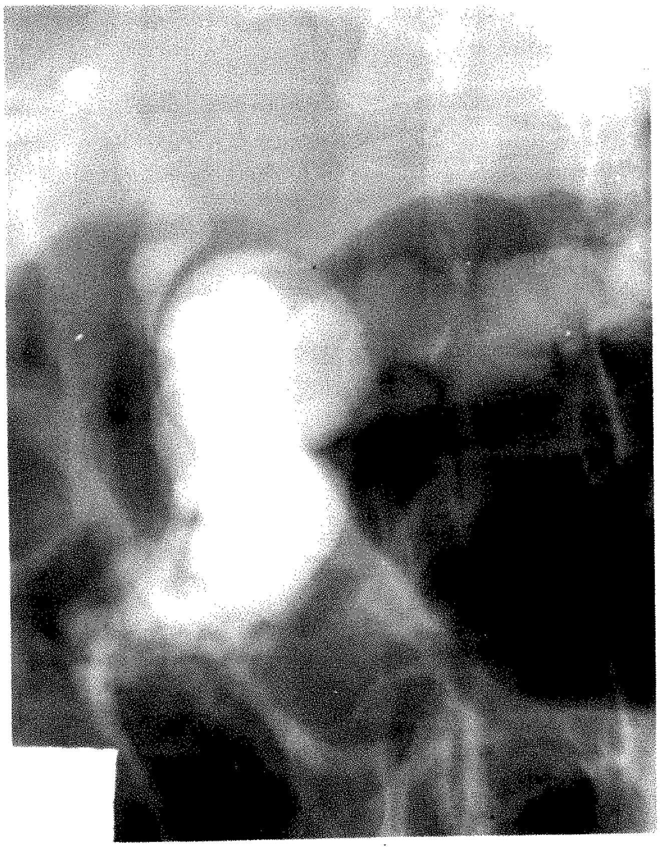

FIG. 3. A 54-year-old white man had weight loss and fatigue. His admission liver function tests were normal. ERCP revealed an intrapancreatic CBD stricture with no proximal CBD dilation. A pseudocyst was seen in the head of the pancreas displacing the CBD. Treatment consisted of a Roux-Y pancreaticojejunostomy (Puestow). Eight-year follow-up revealed no further biliary or pancreatic problems.

creatic procedures were performed in 23 of 38 patients, and consisted of pseudocyst drainage in 13, longitudinal pancreaticojejunostomy in nine (Puestow procedure), and pancreatic biopsy in one patient.

There were four treatment failures as defined by the need for a subsequent biliary procedure. Three occurred in the 18 patients initially undergoing drainage, and one occurred in the patients who did not have BD. One patient required conversion of a cholecystojejunostomy to a choledochojejunostomy subsequent to a severe episode of acute cholangitis, and two patients required choledochoduodenostomies after prolonged T-tube drainage. One patient in the group that did not have BD who experienced a treatment failure returned 4 years after conservative therapy with clinical sepsis, and underwent cholecystectomy, CBDE, and T-tube drainage of the common duct. However, his preoperative sepsis was found at operation to be due to an infected pancreatic pseudocyst, rather than CBD disease. All four of these patients who had treatment failure subsequently did well.

Postoperative Complications

There were no in-hospital deaths. Five major postoperative complications occurred including two subphrenic abscesses, both occurring after Puestow pancreaticojejunostomies; an anastomotic leak that occurred after a Puestow procedure; a peripancreatic abscess after a pancreatic pseudocystogastrostomy and cholecystectomy; and one severe episode of pneumonia.

Liver Histopathology

Intraoperative liver biopsies were obtained in 24 patients (Table 1). Three of 24 biopsy specimens revealed biliary cirrhosis (12%).

Comparison of Patients Who Had BD Versus *No BD*

Table 2 summarizes laboratory and clinical data for patients receiving BD as part of their initial therapy compared with those who did not. Although the mean serum bilirubin and alkaline phosphatase levels were higher in the group undergoing BD, the differences were not statistically significant. The biliary stricture lengths and CBD diameters proximal to the strictured area were nearly identical. The average length of follow-up was also comparable between groups.

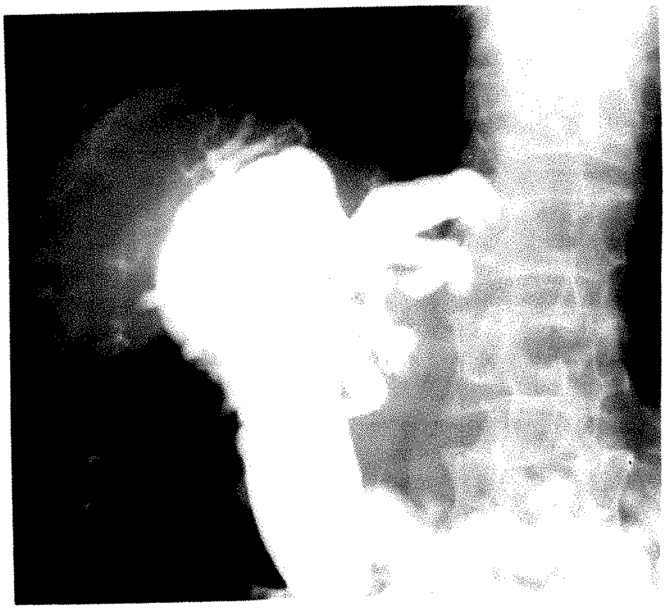

FIG. 4. A 53-year-old white man had abdominal pain. His admission liver function tests were normal. ERCP revealed a 3.0-cm intrapancreatic CBD stricture with a proximal CBD dilated to 4.0 cm. Treatment consisted of a Puestow pancreaticojejunostomy and choledochoduodenostomy. No further problems developed during 26 months of follow-up.

Correlation of Laboratory Values with Cholangiographic Findings

To assess the potential predictive value of laboratory tests for cholangiographic findings, a simple linear regression analysis was performed, and correlation coefficients were determined between four variables (Table 3). There was no significant correlation of either the alkaline phosphatase or the total bilirubin levels with stricture length or proximal CBD diameter. Furthermore, there was no correlation of total bilirubin with alkaline phosphatase levels nor of stricture length with CBD diameter. The disparity between CBD configuration and laboratory values can be appreciated in Figures 1–4.

Hospital Course and Discharge Status (Table 4)

The average hospital stay was 41.7 days, with no difference between the patients who had BD compared with those who did not. The average alkaline phosphatase value at discharge had fallen to approximately 1.5 times normal, and the average total bilirubin level was normal. There was no difference in average discharge laboratory values in the patients who did not have BD compared with those who did.

Follow-up (Table 5)

Six patients were lost to follow-up, leaving 32 patients with an average follow-up period of 4.0 ± 1.0 years. The mean lengths of follow-up for the patients who had BD and for those who did not were 4.4 ± 0.9 and 3.8 ± 1.1 years, respectively. One patient died of acute mesenteric infarction 4.5 years after a cholecystectomy and choledochoduodenostomy. Eight patients had repeated episodes of pancreatitis. A pancreatic abscess developed in one patient 2.5 years after drainage of a pseudocyst, and one patient required drainage of a second pseudocyst. The remaining 16 patients had no further pancreatic or

biliary problems. The frequency of problems was of no greater significance in the patients who did not have BD.

Discussion

Biliary strictures as a consequence of chronic pancreatitis have long been recognized,[10] but until recently were considered unusual. With the increasing use of ERCP, strictures are being identified more frequently. A review of series published over the previous 10 years (Table 6) yields an incidence of biliary stricture in association with chronic pancreatitis in alcoholic patients of 5.7%, with a broad range from 2.7% to 45.6%.[1-3,11-13] Differences in criteria used for patient selection accounts for this wide variation. Currently, controversy remains regarding the natural history of intrapancreatic biliary strictures, the accuracy of preoperative diagnosis, and the appropriate course of treatment. Our study, which contains the largest number of reported patients with biliary strictures treated without surgery, has helped clarify a number of these issues.

The pathologic characteristic of these strictures is one of encasement of the intra- or peripancreatic bile duct in a progressively fibrotic pancreas,[14-17] with edema and inflammation of an acute pancreatitic episode often exacerbating the stricture. The clinical consequences of these strictures can in turn be variable. Many are asymptomatic, with transient or low-grade liver function test abnormalities. Acute episodes of pancreatitis can in turn prompt acute and sometimes sharp elevations of both the serum bilirubin and alkaline phosphatase levels.

The clinical diagnosis of an intrapancreatic common bile duct stricture in a patient with chronic alcoholic pancreatitis is often difficult. There are no definitive signs or symptoms, and liver function test abnormalities may be suggestive but nonspecific. An acute or chronic elevation of the serum alkaline phosphatase level is the most frequent laboratory abnormality, occurring in approximately 80% of patients (Table 6).[3,5] The total serum bilirubin level is also frequently elevated during the acute episodes of pancreatitis, occurring in approximately 65% of patients (Table 6), returning to normal as the acute process subsides, and rarely remaining elevated on a chronic basis.[3,7,14,16,18] Cholangiography, either endoscopic or transhepatic, is the definitive diagnostic tool. Cholangiographic findings, however, are variable, as has been shown in this study and by others.[6,12,14] Previous publications have described these strictures as gradual taperings of the intrapancreatic duct over a distance of 3–5 cm, thereby distinguishing them from the abrupt, short obstructions seen in pancreatic cancer. The exceptions to this rule are sufficiently frequent to render cholangiographic findings dubious in the distinction of these two disease processes.[12]

The correlation of cholangiographic findings with liver function test (LFT) abnormalities was very low in this study, as others have also found.[7,12] In the patients from our study, long strictures with dilated proximal common bile ducts were present despite normal LFTs, whereas short strictures with normal proximal biliary anatomy were seen with remarkably elevated LFTs.

Once a biliary stricture is discovered, the remaining

TABLE 4. *Comparison of Hospital Course and Discharge Laboratory Values in Patients with and without Operative Biliary Drainage*

	Drainage	No Drainage
Length of stay (days)	42.0 ± 4.4	41.0 ± 4.6
Average discharge alkaline phosphatase level (IU/L; normal: 21–91 IU/L)	150.0 ± 39.0	154.0 ± 19.0

* Of 38 patients with chronic alcoholic pancreatitis, 11 were found to have intrapancreatic CBD strictures by ERCP.

† Of 651 admissions for chronic alcoholic pancreatitis from January 1968 through December 1979, 21 patients had surgery for intrapancreatic CBD strictures.

‡ Of 300 patients with chronic alcoholic pancreatitis from 1972 through 1979, 24 were found to have intrapancreatic CBD stricture.

§ Of 79 consecutive patients with moderately severe chronic pancreatitis who had ERCP, 36 were found to have stenosis of the intrapancreatic CBD.

‖ Of 1262 patients with chronic pancreatitis admitted from 1970 through 1982, 51 of these patients were treated for distal CBD obstruction.

¶ Of 151 patients admitted for chronic alcoholic pancreatitis from 1979 through 1984, 15 were found to have a stricture of the intrapancreatic CBD by cholangiography.

decisions involve the proper therapeutic choice(s). Concerns over the possible development of acute cholangitis and/or biliary cirrhosis have in the past prompted *early* surgical drainage of the proximal biliary tree.[4,5] More recent recommendations are to delay drainage until problems manifest themselves.[3,6,7,15,16] This latter approach is supported by low rates for cholangitis and biliary cirrhosis reported by ourselves and others (Table 6).

The decision to delay drainage of a CBD stricture due to pancreatitis must be based on an assessment of the risk in conservative or expectant management of this lesion. Although no study specifically addresses nonsurgical treatment of biliary strictures in chronic pancreatitis, there are small cohorts of patients who for various reasons did not have surgical therapy of their biliary strictures.[1-3] Scott et al.[2] reported on 11 patients with chronic alcoholic pancreatitis and intrapancreatic CBD strictures. Five of these patients had no surgery, and for a follow-up of 1 year or more, had no further problems. Yadegar et al.[3] followed two patients with known strictures and chronic elevations of alkaline phosphatase levels for 5 years, obtaining several subsequent liver biopsies. No disease progression was discovered in either patient histologically or clinically, and there was no mention of the occurrence of cholangitis. Afroudakis and Kaplowitz[1] reviewed liver histology from 24 patients with known CBD strictures due to chronic alcoholic pancreatitis, and found that three of these patients had disease progression to biliary cirrhosis over an unspecified period after the initial diagnosis. Our study contains the largest single collection of patients with known biliary strictures who did not have surgical therapy. These 20 patients were followed for an average of 3.8 years with no increased morbidity compared with those patients initially undergoing BD, despite clinical and cholangiographic disease of comparable severity.

Based on the above findings, we believe that the presence of a stricture should not be the sole indication for surgical intervention. Absolute indications for surgical intervention are acute cholangitis, biliary cirrhosis, and protracted jaundice.[3,4,7,8,14-16,19,20] Based on previous and current findings, there are two relative indications for operative biliary drainage: in patients with diagnosed strictures in whom a pancreatic procedure is already planned,[7] and in patients with known strictures and a previous history of cholangitis. The presence of a dilated CBD proximal to a stricture and/or a chronically elevated alkaline phosphatase level do not justify surgical intervention, but most certainly warrant long-term follow-up consisting of periodic liver function tests, cholangiography, and liver biopsies.[3,16] Once operative biliary drainage is indicated, we recommend choledochoenterostomy over cholecystoenterostomy or T-tube drainage. Results of our study and of others suggest that cholecystoenterostomy does not offer sufficient or reliable long-term drainage.[3,5,7,8,14] Prolonged T-tube drainage in two of five patients in our study necessitated revisions to choledochoenterostomies. This problem has also been reported by others.[4,14]

In summary, we present 38 patients with chronic alcoholic pancreatitis and ERCP-proven intrapancreatic biliary strictures. Twenty of the 38 patients did not have surgical therapy, with no increase in morbidity compared with the 18 patients who had surgery, despite disease of equivalent severity. Based on these findings, we believe that asymptomatic biliary strictures in patients with chronic pancreatitis can be safely observed, with periodic evaluation using liver function tests, ERCP, and liver biopsies. Absolute indications for surgery are acute cholangitis, biliary cirrhosis, and persistent jaundice. Relative indications for biliary drainage include a planned pancreatic procedure and a previous history of cholangitis in a patient with a known stricture.

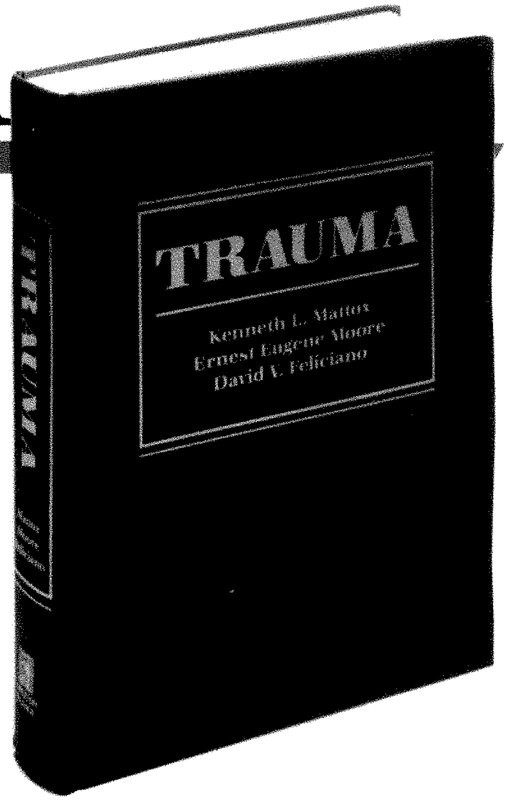
Announcing the new definitive reference on

TRAUMA



Recognizing the need for a comprehensive reference on the increasingly important and growing field of trauma care, three of the nation's leading trauma surgeons gathered over 100 surgeons and physicians to write in their specific areas of expertise. The result of their effort is this outstanding volume on the care of the victim of traumatic injury.

The book covers all aspects of trauma care, emphasizing current approaches. In addition to describing surgical techniques, it provides in-depth information on: how to design and set up trauma center...prehospital services... triage systems...rehabilitation, and much more!

Sections: *Foreword by Alexander J. Walt*. Trauma Overview. General Principles and Patterns. General Management of the Trauma Patient. Management of Specific Injuries. Special Problems in Trauma. Complications of Trauma.

Order your copy of this important new book today. Review it with no obligation to buy for 30 days. We're sure you'll agree that this is the text-reference any professional involved in the care of the trauma patient must own!

New, for Surgeons

Surgery Annual 1988

Series Editor: Lloyd M. Nyhus, M.D., Warren H. Cole Professor and Head of the Department of Surgery at the University of Illinois College of Medicine; Surgeon-in-Chief, University of Illinois Hospital, Chicago

Surgeons rely on the **Surgery Annual Series** to keep them current with the most important developments in the surgical management of disease and the latest advances in the basic sciences as they relate to the practice of surgery. Each handsome volume contains a collection of original articles representing a worldwide exchange of ideas.

Join your colleagues who receive the Annual as it is published each year. When you enroll in our convenient **Standing Order Plan** for the series, we'll send you each new volume to examine free for 30 days. To enroll, mention the Standing Order plan when you call or write.

Publ. Jan. 1988, 384 pp. (approx.), illus., hardcover, ISBN 0-8385-8728-3, A8728-6, $65.00 (approx.)

Current Surgical Diagnosis and Treatment

Eighth Edition

edited by Lawrence W. Way, M.D., University of California School of Medicine, San Francisco

Concise, current, complete and authoritative, this popular reference gives you the full value you've come to expect from **Lange Medical Publications**. The text emphasizes quick recall of major diagnostic features and brief descriptions of disease processes, followed by procedures for definitive diagnosis and treatment.

Some of the new information in this 1988 edition

- The latest concepts of enteral and parenteral feeding and the metabolic consequences of starvation, trauma and sepsis
- Recent concepts of etiology, the approach to diagnosis, and staging of head and neck cancers
- New techniques for managing bleeding varices and hepatic encephalopathy
- Discussion of esophageal perforation, corrosive esophagitis, and Barrett's Syndrome
- New section on carotid body tumor and updated concepts of Raynaud's syndrome, thoracic outlet syndrome, and Takayasu's arteritis.

Publ. Jan. 1988, 1,196 pp. (approx.), illus., flexibound, ISBN 0-8385-1415-4, A1415-7, $34.50 (approx.)

INCOMPARABLE MOSS®TUBES ....

(but compare with other feeding-decompression tubes anyway.)

1. Decompression Site

Gastric suction alone cannot work! The stomach's longitudinal folds mimic parallel segments of intestine. Aspiration orifices may empty a single "Magenstrasse" (figure A). Most swallowed air avoids suction, and is propelled through the pylorus via adjacent channels. A clinical study of other N-G and G-tubes measured 32-42% inefficiency. *A toll booth in the center of a wide highway cannot collect from traffic in the outer lanes.*
Removal of air is most effective at constricted (single-file) sites. Measured efficiency increases 12-fold by adding aspiration within the adjacent esophagus and/or duodenum. And flowing duodenal digestive juices "self-cleanse" the tube of occluding mucus.

2. Feeding site

Gastric feeding risks distention and aspiration. **Jejunal** delivery bypasses 1-3 feet of proximal intestine, acting as a barrier to retrograde decompression. Aspiration of feedings is less likely, but remains a risk. Minimal initial infusion (starvation) is manditory initially.

The **Moss®G-Tube's duodenal** delivery site is the most effective. With proximal duodenal aspiration (patented), the initial distal feeding rate is unlimited. Clinical x-rays visualized removal of all excess feeding, with none reaching the stomach. (Fig. B) The full length of intestinal absorption is available immediately. Earliest "enteral hyperalimentation" is safely instituted within the recovery room. Positive nutritional balances are achieved, leading to enhanced sepsis resistance, accelerated wound healing and shorter L.O.S.

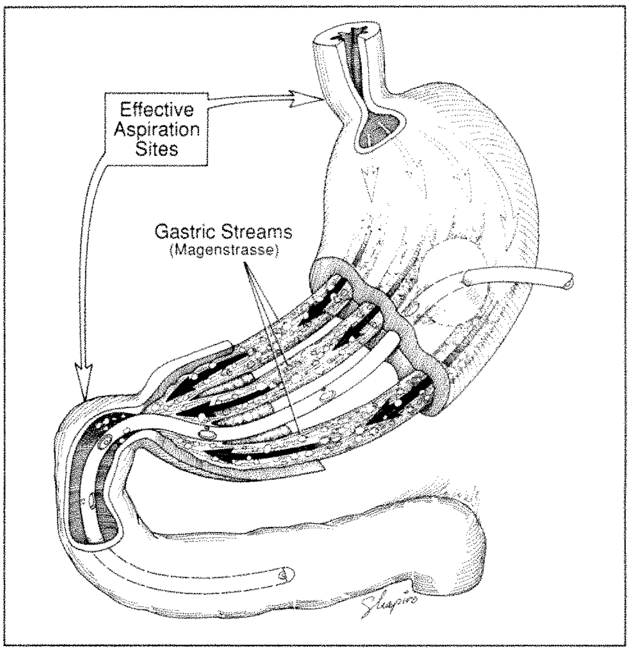
3. Aspiration Orifices

Uniformly sized orifices (**all others**) "suck in" mucosa to occlude the openings and stop decompression. Mucosal release then requires a null period (intermittant suction). Prograde air or retrograde feedings can be propelled accross and beyond the stomach, causing distention or aspiration.

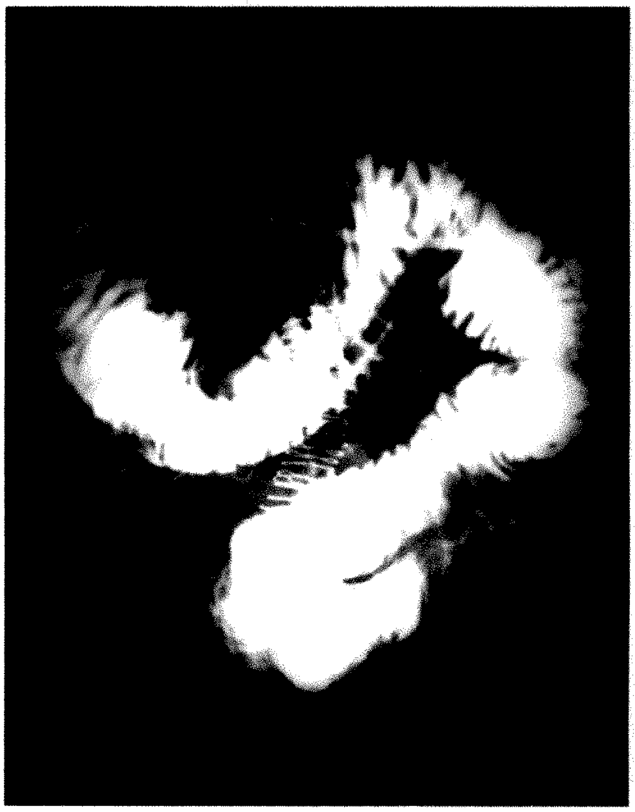
By pairing each large orifice with a patented, smaller "suction buster"®opening (**Moss®G-tube**), continuous aspiration is maintained despite inadvertantly elevated suction.

4. Biomaterials

The **Moss®G-Tube** is **all silicone**, the accepted "gold standard" for optimum long term stability, tissue tolerance and biocompatibility.



A. The functioning stomach subdivides into discrete"Magenstrasse". **Any** tube can only evacuate the single gastric stream within which it lies.



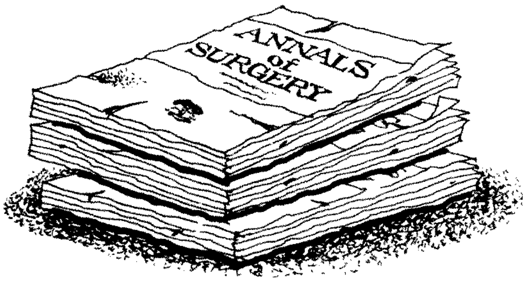
B. Study @ 5 minutes. Note effective removal of all excess barium flowing retrograde, none visualized to reach the stomach.

New for 1987

For your professional library

Bound volumes of

Annals of Surgery



Long after your personal copies of ANNALS OF SURGERY have been read, shared with your office staff, used up and worn out, you can have instant access to the unique and valuable information in back issues of this distinguished journal by ordering bound volumes.

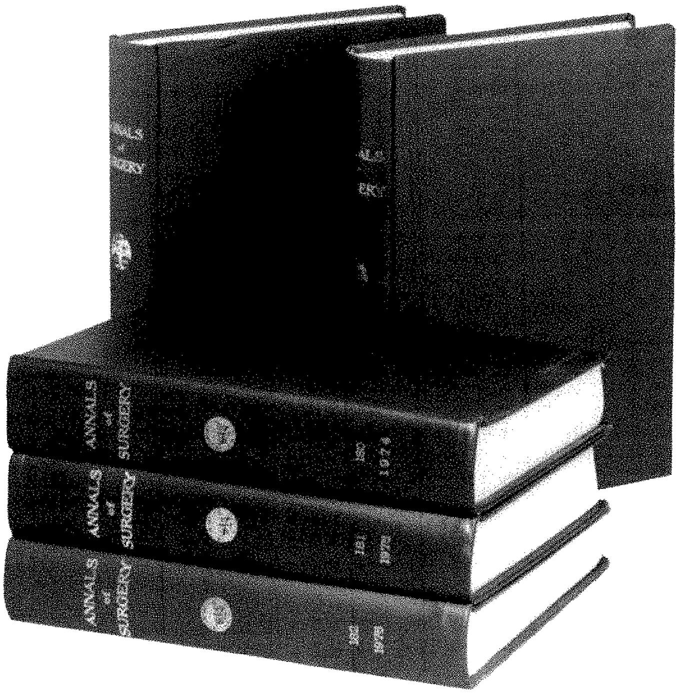
Your bound volumes give you a permanent and comprehensive reference for changes and advances in your specialty—a source that will grow and increase in usefulness over the years. Each volume features:

- all text pages of every issue, including the complete author and title indexes
- no advertising—only professional, clinically pertinent material (a space-saver on your bookshelves)
- handsome, durable bindings in maroon buckram, with the journal name, year, and volume number imprinted in gold on the spine

No need to return your personal copies to us, or to go to the trouble and expense of having them bound locally. We over-run copies of each issue in order to have sufficient quantities on hand. But we must tell our printer how many we need, so please let us know right away.

You must be a current subscriber to take advantage of this bound volume offer.

Use the convenient coupon to order your 1987 volumes today. They will be on their way to you shortly after the publication of the final volume issue.



Yes! Please send me the 1987 bound volumes of **Annals of Surgery** (65-98635/65-98643) for $49.00 U.S. ($59.00 elsewhere).

Extravascular Lung Water as an Indicator of Pulmonary Dysfunction in Acute Hemorrhagic Pancreatitis

CATHY A. BURNWEIT, M.D. and JURETA W. HORTON, PH.D.

From the Department of Surgery, The University of Texas Health Science Center at Dallas Southwestern Medical School, Dallas, Texas

This study quantifies lung water in acute hemorrhagic pancreatitis to determine the degree to which pulmonary dysfunction occurs subclinically, before alterations in the arterial blood gases can be measured. Pancreatitis was induced in ten dogs by injecting 0.5 ml/kg of bile into the pancreatic ducts, which had been surgically cannulated. Pulmonary and systemic blood gases and blood pressures, heart rate, extravascular lung water, and lung blood flows were studied over 5 hours while cardiac output and mean arterial pressure were maintained at control values by Ringer's lactate infusion. The percentage of water in lung tissue was determined at the time of sacrifice using gravimetric measurements. Mean arterial pressure, cardiac output, and pulmonary capillary wedge pressure, reflecting intravascular volume status, did not change through at the experiment. By contrast, major disturbances were measured in the pulmonary bed with pulmonary artery pressures rising from 15.6 ± 1.8/8.1 ± 1.3 mmHg to 22.0 ± 1.2/15.6 ± 1.7 mmHg over 5 hours ($p < 0.01$). Peripheral vascular resistance rose from 3.6 ± 0.6 units to 6.6 ± 0.4 units ($p < 0.05$), whereas bronchial blood flow to the lung fell significantly. These changes in pulmonary hemodynamics were not reflected by changes in the arterial blood gases. Arterial oxygenation was maintained during 5 hours of pancreatitis. The partial pressure of carbon dioxide and the serum pH did not change significantly. There was, however, a progressive rise in extravascular lung water measured by the double-dilution technique from 10.2 ± 0.8 ml/kg at control to 18.1 ± 2.8 ml/kg ($p < 0.01$) at 5 hours. This was confirmed by direct gravimetric measurements, which revealed an increase in the water content of the lung from 78.1 ± 0.3% to 86.4 ± 2.4% over the course of the experiment. Arterial blood gases, therefore, do not necessarily reflect the pulmonary deterioration in acute pancreatitis. These data supported a mechanism of lung dysfunction independent of the circulatory compromise, which often accompanies the disease in the clinical setting.

IN HEMORRHAGIC PANCREATITIS, serious lung complications occur in over 50% of patients.[1,2] The respiratory dysfunction that accompanies the disease can range from a mild oxygenation defect to a fatal adult respiratory distress syndrome. Patients with acute pancreatitis may have massive third-space sequestration of fluid and usually present in moderate to severe hypovolemic states. Whether the pulmonary deterioration in pancreatitis results from the response of the lung to circulatory compromise, which effects patients before fluid resuscitation, or to humoral and reflex effects specific to the injured pancreas is unknown. The respiratory defect is usually first signaled clinically by aberrations in arterial blood gases and later by changes in the chest radiograph. This study involved the measurement of lung water in a canine model of pancreatitis to determine whether, in the absence of the usual clinical signs of lung dysfunction, significant occult derangement of pulmonary physiology occurs. By strictly maintaining hemodynamic parameters at control values from the onset of the pancreatic insult, we attempted to resolve whether the pulmonary defect emanates from hypovolemia and shock or from mechanisms unique to pancreatitis.

Methods and Materials

Ten large mongrel dogs (mean weight: 23.4 ± 1.5 kg) were housed for several days in individual cages until a normal complete blood count and a negative screen for microfilaria were obtained. All animals were free from acute gastrointestinal and upper respiratory disease. The animals were allowed water intake *ad libitum* but no food starting 12 hours before the experiment. After sedation with intramuscular acepromazine (0.005 mg/kg), a peripheral venous catheter was placed. Intravenous sodium pentobarbital (15 mg/kg) was administered to induce anesthesia. Each dog was incubated and allowed

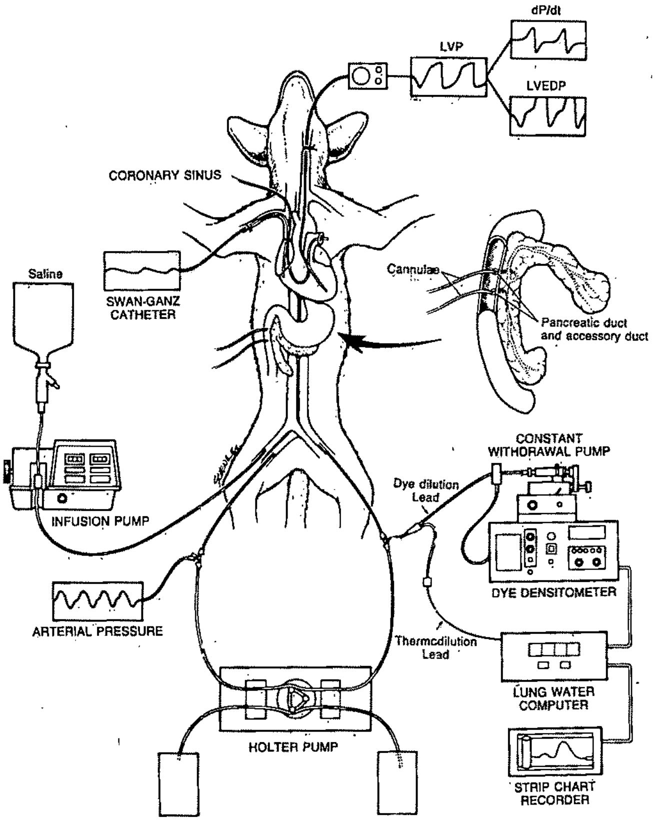

FIG. 1. Instrumentation of a dog before induction of pancreatitis.

to breath spontaneously. Alpha-chloralose (50 mg/kg) in solution with polyethylene glycol 200 was given intravenously to maintain anesthesia. Supplemental doses were used as necessary over the course of the experiment.

Each animal was instrumented as indicated in Figure 1. A 16-gauge catheter was placed in the femoral vein for fluid administration and blood withdrawal. Both femoral arteries were catheterized for continuous blood pressure recording (Statham pressure transducer, Model P23ID, Statham Gould Medical Products Division, Oxnard, CA, and Siemen's micrograph recorder, Model 81, Siemens, Iselin, NJ) and for simultaneous blood withdrawal for use in regional blood flow measurements with the microsphere technique. A microtipped, pressure-sensitive transducer (#7 French, Model CP470, Millar Instruments, Inc., Houston, TX) was introduced into the left ventricle by retrograde cannulation of the left common carotid artery for injection of microspheres and for measurement of left heart pressures.

The right femoral artery was cannulated with an Edwards Laboratory lung water catheter (Model 96-020-5F). This catheter was attached to a Gilford syringe pump (Model 105-S) to allow blood withdrawal through the cardiac output dye-densitometer (Waters Instruments, Model COR-100, Waters Instruments, Rochester, MN) during extravascular lung water determination. A balloon-tipped Swan-Ganz catheter (Model 93A-831H-7.5F, American Edwards, Division of American Hospital Supply, Irvine, CA) was threaded *via* the left internal jugular vein through the right side of the heart and into the pulmonary artery. Its position was confirmed initially by fluoroscopic examination and subsequently by wave form monitoring. Systemic anticoagulation was induced by the administration of intravenous heparin (100 units/kg) and maintained with supplemental doses of 50 units/kg/h.

Intravenous lactated Ringer's solution was begun (10 ml/kg) during instrumentation to account for overnight volume depletion from fasting. Each dog underwent celiotomy through a midline incision. An anterior enterotomy was made in the second portion of the duodenum. The main and accessory pancreatic ducts were individually cannulated with long 20-gauge catheters that were secured with silk pursestring sutures. Bile was withdrawn from the gallbladder by direct needle puncture of the organ and injected (0.5 ml/kg) into the main pancreatic duct. This was performed under direct vision to assure bile staining of the entire pancreas and to verify no leakage from the ampullae. The catheters were occluded with stop cocks and left in place in the abdomen. The duodenal and abdominal incisions were closed. Animals were followed for 5 hours after the induction of pancreatitis.

Control and systemic blood pressures, heart rate, pulmonary wedge pressure, and cardiac output using both the thermodilution and cardiogreen dye dilution techniques were measured before the induction of bile pancreatitis. Stroke volume was determined from heart rate and cardiac output. Pulmonary vascular resistance was calculated. During 5 hours of pancreatitis, these parameters were studied hourly. In addition, cardiac output and systemic blood pressures were measured every 15 minutes so that the rate of lactated Ringer's administration could be adjusted to maintain these parameters at control levels.

Pulmonary and peripheral artery blood gases were measured (Model ABL-3, Radiometer American Inc., Dallas, TX) before the induction of biliary pancreatitis and hourly thereafter. Amylase and creatinine levels were measured during the control period and at 2 and 5 hours to assure the production of a significant pancreatic injury and to obtain some indication of the state of hydration of the animal.

Two methods of measuring lung water were used. In the double-indicator dilution technique described by Lewis and Elings,[3] a cardiogreen dilution curve was compared with the dilution curve of iced saline by a microprocessing digital computer (American Edwards Laboratory Lung Water Computer, Model 9310) to determine the size of the extravascular fluid compartment in the lungs. In addition, the dry/wet weight ratio of normal dog lung was compared with that of dogs 5 hours after the induction of bile pancreatitis to show the change in percentage of water of the pulmonary parenchyma.

Nutritive lung blood flows were measured hourly using a microsphere technique. Six radioactive labels, I-125, Nb-95, Sc-46, Sr-85, Co-57, and Sn-113 (New England Nuclear, Boston, MA), measuring 15 μm in diameter were used. For each measurement of flow, a bolus of labeled microspheres (approximately 1.5 million) was injected into the left ventricle and the catheter flushed with 10 ml of warm saline. Simultaneous with the injection of microspheres and continuing for 120 seconds, duplicate reference blood samples were obtained from the femoral arteries at a constant withdrawal rate of 12 ml/min (Holter Pump, Model 911, Critikon Laboratories, Tampa, FL). Five hours after the induction of pancreatitis, the animals were killed by an overdose of barbituates according to the guidelines set by the National Institutes of Health and by the University of Texas Health Science Center Faculty Committee for Animal Use. Lung and kidney tissue was harvested, and blood and tissue samples were weighed to the nearest milligram and counted for 5 minutes in a multichannel autogamma scintillation spectrometer (Model 5320, Packard Instrument Co., Laguna Hills, CA). For each set of samples, vials containing aliquots of each microsphere were used to determine the energy level setting on the scintillation counter. From the standards of each microsphere used to set the energy level and the blood samples containing the highest count of microspheres injected, the cross-talk fraction or overlap of gamma energy was calculated for each of the microspheres. The contribution of overlap of gamma energy of each microsphere was subtracted and a nuclide reference factor (ml/min/count) was calculated. For each tissue sample, the background counts were subtracted and the counts for each isotope were multiplied by the nuclide reference factor to obtain mean blood flow rate. Only animals with less than 15% disparity between right and left kidney flows were used for data analysis. Flows were calculated using a DEC-10 computer program (Digital Equipment Corporation, Maynard, MA) and expressed as ml/min/g.

At autopsy the gross appearance of the lung was noted and tissue for dry/wet weight ratios and blood flow studies was harvested. The proper placement of intrathoracic catheters was verified. In the abdomen, the bowel was examined and the presence and quantity of ascites were noted. The appearance of the pancreas and retroperitoneum with respect to hemorrhage, necrosis, accumulation of edema, and tissue saponification was recorded.

TABLE 1. *Systemic Hemodynamic and Metabolic Parameters*

	Control	2-Hour	5-Hour
MAP (mmHg)	88 ± 5	89 ± 9	92 ± 8
HR (beats/min)	110 ± 5	102 ± 5	102 ± 6
CO (ml/kg/min)	131 ± 7	162 ± 15	128 ± 9
Stroke volume (ml/kg)	1.18 ± 0.09	1.28 ± 0.11	1.26 ± 0.13
PCWP (mmHg)	5.3 ± 0.6	5.7 ± 1.6	5.6 ± 0.4
Amylase (mg/dl)	631 ± 77	3575 ± 1644*	1505 ± 223*
Creatinine (mg/dl)	1.0 ± 0.1	1.1 ± 0.9	1.0 ± 0.1
Hgb (g/dl)	12.2 ± 0.6	10.3 ± 0.9	8.3 ± 0.5*

* Significant difference from control, $p < 0.05$.

All data are presented as mean ± SEM. A two-way analysis of variance and a Newman-Keuls test were used to evaluate significant differences between groups with regard to hemodynamic and metabolic parameters and changes in regional blood flow. Differences were considered significant at $p < 0.05$.

Results

Systemic Hemodynamics

Over the 5 hours after induction of pancreatitis, hemodynamic parameters were maintained at control values by crystalloid administration. The mean arterial pressure was stable near the control value of 88 ± 5 mmHg and the heart rate did not change significantly over the course of the experiment from the prepancreatitis value of 110 ± 5 beats/min (Table 1). Similarly, despite the extensive third-space fluid losses common in hemorrhagic pancreatitis, cardiac output and stroke volume were kept constant by lactated Ringer's solution infusion. The pulmonary capillary wedge pressure, an indicator of left ventricular filling pressure and preload, was not altered from the control level of 5.3 ± 0.6 mmHg, demonstrating the stable intravascular volume status throughout the experiment.

Metabolic Indicators of Pancreatitis

The metabolic data are also presented in Table 1. The gross alterations in the pancreas seen directly after injection of autologous bile into the pancreatic duct were reflected by rising serum amylase levels. The amylase level rose 467% by 2 hours and was still 139% above control levels at 5 hours after the induction of pancreatitis. The creatinine level was unchanged from the control value of 1.2 mg/dl over that period. Neither arterial pH nor serum bicarbonate levels were altered over the course of 5 hours, indicating an absence of significant uncompensated acidosis after the pancreatic insult. The hemoglobin level, however, fell to 84% of control values by 2 hours and was 68% of the peak prepancreatitis value at 5 hours ($p < 0.05$).

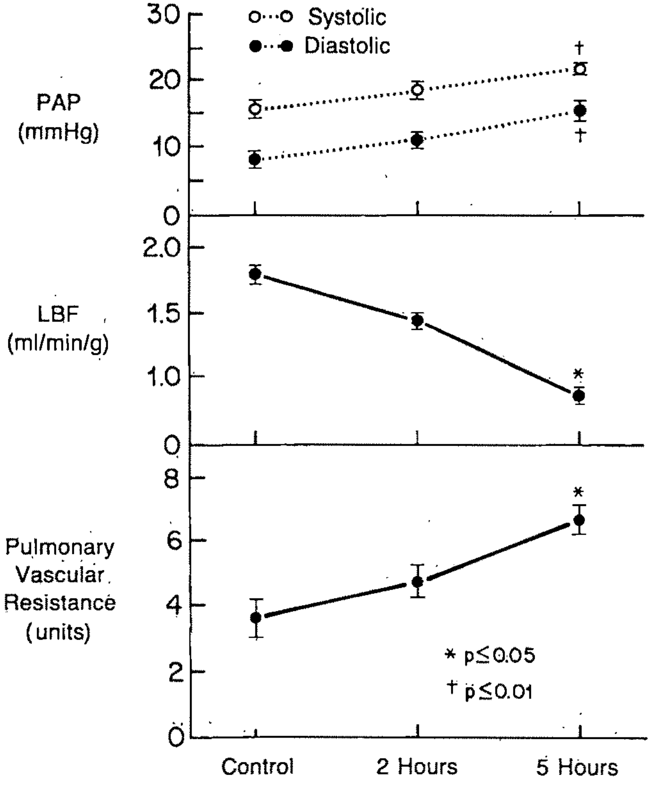

FIG. 2. Pulmonary hemodynamics over 5 hours after the induction of pancreatitis. †p ≤ 0.01; *p ≤ 0.05.

Pulmonary Hemodynamics

Whereas systemic cardiovascular parameters were largely unchanged over 5 hours of pancreatitis, major hemodynamic disturbances were measured in the pulmonary system (Fig. 2). Pulmonary artery systolic pressures rose 41% and diastolic pressures rose 93% over the course of the experiment, and this elevation reached significance at 5 hours. Pulmonary vascular resistance was elevated by 2 hours and continued to rise until the end of the study when an 83% increase above control levels was noted. A concomitant fall in lung blood flow, to 46% of control values, was measured at 5 hours ($p < 0.05$).

Gas Exchange and Extravascular Lung Water

Although significant changes in the hemodynamic functions of the lung were measured, the diffusing capacity of the lung was not greatly impaired over 5 hours of pancreatitis, as demonstrated in Table 2. Partial pressure of oxygen did not change significantly from the control value of 111 ± 8 mmHg. There was a slight but not significant decrease in partial pressure of carbon dioxide over the course of the experiment. Pulmonary artery oxygen content was maintained over the initial 2 hours of the study, but fell significantly to 76% of control values by 5 hours. This most likely reflects the increased oxygen extraction in the periphery from the stress of the pancreatic insult.

TABLE 2. *Arterial Blood Gases*

	Control	2-Hour	5-Hour
pH	7.32 ± 0.03	7.34 ± 0.03	7.30 ± 0.04
pO_2 (mmHg)	111 ± 8	120 ± 10	111 ± 10
pCO_2 (mmHg)	35 ± 3	32 ± 2	31 ± 1

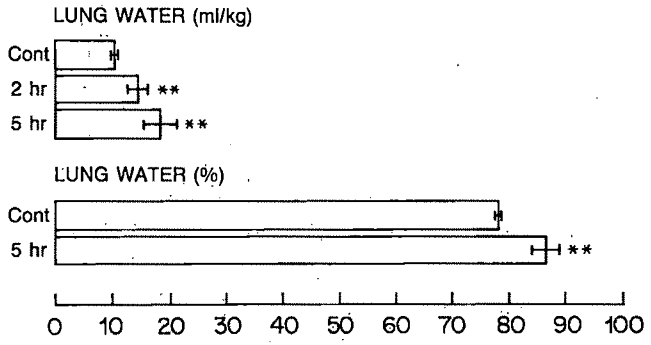

FIG. 3. Extravascular lung water and water composition of pulmonary parenchyma over 5 hours of pancreatitis. *p < 0.05; **p < 0.01.

Despite the lack of impairment of pulmonary gas exchange, extravascular lung water measured by double dilution curves increased progressively from the control value of 10.2 ± 0.8 ml/kg over the 5-hour study (Fig. 3). The 40% rise in extravascular water noted at 2 hours reached significance at the $p \leq 0.05$ level, whereas an 80% rise over control ($p < 0.01$) was measured at 5 hours. The rise in lung water was confirmed by the altered dry/wet ratios of lung tissue at sacrifice.

Autopsy Findings

No animal died before completion of the study. The postmortem examinations of animals with autologous bile-induced pancreatitis revealed several abnormalities. All animals showed gross evidence of acute pancreatitis with changes in the pancreatic bed. The retroperitoneum was massively edematous in all animals, with pancreatic hemorrhage and frank saponification noted in nine of 10 animals. Dilated, boggy small bowel and acites were present in all dogs at sacrifice, with more than half the animals sequestering over 500 ml of intraperitoneal fluid.

Frank pulmonary consolidation was evident in all animals with dependent areas of the lungs being the most affected. Despite the low pulmonary capillary wedge pressures measured, nine of 10 animals had frothy sputum evident in the endotracheal tube at or before sacrifice.

Discussion

The quantification of extravascular lung water was described 30 years ago by Chinard and Enns,[4] who used a technique of measuring the diffusion of radioactive isotopes into the pulmonary parenchyma. This method correlated poorly with actual gravimetric measurements of lung water, however, because of slow molecular diffusibility, especially with extensive pulmonary edema. Another drawback of the technique was that accuracy varied greatly with changes in cardiac output. In the 1970s, extravascular lung water was quantified with double-indicator dilution techniques using thermal dilution,[5–7] which is a hundred times faster than molecular diffusion.[3] This method had the benefit of being reproducible, repeatable without blood loss, nontoxic, and had minimal[8,9] or no[10] dependence on filling pressures and cardiac output. The clinical applicability of the method was restricted, however, as the curves for thermodilution and green dye dilution required integration and comparison by hand. With the development of the microprocessing digital computer that performed the cumbersome mathematics, Lewis and Elings[3] advanced a technique for measuring extravascular lung water that could be carried out easily and rapidly at the bedside. The reproducibility of multiple green dye thermodilution determinations of extravascular lung water is within 8%.[11] Some studies have suggested a slight overestimation (10–20%) of extravascular lung water by double-dilution techniques because of the similar heat diffusion capacities of certain nonaqueous lung tissues[13,14]; however, other studies have failed to confirm these data.[10] Regardless of this disagreement, the measurement using double-dilution methods mimic those of lung water by gravimetric techniques with a correlation coefficient of greater than 0.9.[10,12,15–17]

Enquist and Gliedman[18] reported that respiratory failure was the cause of death in 20% of patients dying of acute pancreatitis, and pulmonary disease contributed to the death of another 40% of such patients. Despite the initial paucity of roentgenographic and clinical findings of pulmonary failure in patients with acute pancreatitis, a mild to moderate degree of respiratory insufficiency may be demonstrated in over half the patients by measuring the arterial blood gases.[19] We have attempted to demonstrate that the pulmonary changes involved in the disease process occur long before aberrations in gas diffusion can be measured.

Our study confirms the hemodynamic derangements of the pulmonary bed that have been reported by others in acute pancreatitis.[20–22] A significant pulmonary hypertension is noted along with a major rise in vascular resistance and a decrease in the bronchial blood flow to the lung. In this study, all of these conditions are noted within 2 hours of the onset of the pancreatic insult and often as early as 30 minutes after the induction of pancreatitis; abnormal gas exchange was still not detected 5 hours after the onset of pancreatitis.

The rise in extravascular lung water, measured noninvasively by the double indicator dilution technique, likewise occurred in rapid sequence after the onset of pancreatitis. This increase in extravascular lung water was progressive and appeared unrelated to left ventricular filling pressures. Although elevated pulmonary capillary wedge pressures in pancreatitis have been reported sporadically,[22,23] the larger body of experimental and clinical work confirmed the low or normal values reported in this study.[21,24–26] The gross pulmonary edema of pancreatitis, which was noted in 90% of the dogs in this study, has been studied by Warshaw et al.[25] and Lee et al.[21] The lung edema of pancreatitis is an exudative fluid with a high protein content, which further supports an increase in pulmonary endothelial permeability rather than a transudative, pressure-related phenomenon.

The mechanism of injury to the capillary alveolar membrane in pancreatitis is not well delineated. Clearly, the accumulation of excess extravascular lung water in pancreatitis is not solely related to hypovolemia and shock, which was prevented in this canine model, nor to a hypoxic injury, since the partial pressure of oxygen never fell during the current study. The release of lecithinase (phospholipase A) from the pancreas with the subsequent destruction of pulmonary surfactant and the development of atelectasis and fluid exudation has been proposed[27–29] as a mechanism of injury. Elevated triglycerides and their breakdown to free fatty acids, which have a toxic effect at the alveolar level, have been implicated in the pulmonary injury of pancreatitis.[25,30,31] Bradykinin and kallikrein, vasodilatory substances believed to be activated by the release from the pancreas of trypsinogen and kallikreinogen during the acute phases of pancreatitis, may play a role in the systemic effects of pancreatitis.[32,33] The above-mentioned mechanisms of pulmonary insult are all direct; that is, the injury would appear to be a result of direct contact between an offending substance and the lung. The role of indirect mechanisms of pulmonary injury, that is, those requiring the participation of an intermediary such as polymorphonucleocytes or complement, is still largely unknown in acute pancreatitis.[34]

Extravascular lung water measurement requires nothing more invasive than the usual minimal monitoring devices in a critically ill patient, *i.e.*, central venous access and a peripheral artery line. Whether this technology develops into a useful clinical adjuvant for signaling pulmonary dysfunction earlier in the course of pancreatitis than do the arterial blood gases currently remains to be seen. As of now, the quantification of extravascular lung water remains a sensitive research tool for the monitoring of pulmonary dysfunction in a variety of disease states.

Summary

From this study it is clear that the respiratory deterioration in hemorrhagic pancreatitis results not from the response of the lung to hypovolemia and shock but from humoral or reflex effect specific to the diseased pancreas. Although mean arterial pressure, cardiac output, and pulmonary capillary wedge pressure were maintained at control values, major hemodynamic disturbances were noted in the pulmonary bed. These included a rise in pulmonary vascular resistance, a fall in the nutritive blood flow to the lung, and a significant pulmonary hypertension. These changes were not reflected in the arterial blood gases, which showed that partial pressures of oxygen and carbon dioxide were maintained at control values, as was the acid-base status of the animal. Lung water, measured using two different methods, rose progressively over the first 5 hours of pancreatitis, demonstrating clearly that the arterial blood gases do not necessarily reflect the pulmonary deterioration early in the course of acute pancreatitis.

The Complications of Pancreatectomy

MICHAEL TREDE, B.A., B. CHIR., M.D., HON.F.R.C.S.(ENG.) and GUNTHER SCHWALL, M.D.

From the Surgical Clinic, Mannheim, University of Heidelberg, Mannheim, West Germany

This paper analyses the early postoperative complications after 285 pancreaticoduodenectomies performed during the past 15 years in the Surgical University Clinic, Mannheim. There were 235 partial (Whipple) and 52 total pancreatectomies performed for pancreatic and periampullary tumors (181 patients) and complicated chronic pancreatitis (104 patients). A total of 92 complications requiring relaparotomy in 42 patients ended fatally in nine patients. The overall operative and hospital mortality rate was 3.1%. The most frequent and most dangerous were complications at or around the pancreaticojejunal anastomosis, which occurred 25 times with five deaths. Postoperative hemorrhage was seen in 16 patients; endoscopic treatment in four patients and operation in 12 patients was successful in stopping the bleeding in all but one patient. Eight biliary fistulae either ceased spontaneously (3 patients) or after operative reintervention (5 patients) without any mortality. Control of these complications depends on four lines of approach: (1) *before* operation: optimal preparation of the jaundiced patient including endoscopic transpapillary decompression of the common duct; (2) *during* operation: a meticulous and standardized technique is mandatory; (3) *after* operation: continous observation in the surgical intensive care unit is essential for the timely detection of possible complications; and (4) early reintervention can salvage the great majority of these patients with deleterious complications.

EVEN IN THE LAST QUARTER of the 20th century, pancreatectomy remains one of the most formidable abdominal operations for the surgeon. Originally performed in 1909 by Kausch in Berlin,[1] it was perfected and popularized by Whipple in 1934,[2] and has since found its way into most surgical departments all over the world. Lionized by some surgeons as the "cadillac of abdominal surgery,"[3] morbidity and mortality of this operation are so formidable that others have abandoned it altogether.[4,5] Yet, others (albeit not very seriously) are trying to have it banned by law.[6]

In this paper we intend to take on this argument by analysing the postoperative complications after 285 pancreatectomies. The lessons we learned from this experience hopefully will be of some use to the reader.

Materials and Methods

To put these complications into perspective, the overall results of 285 pancreatectomies are presented in Table 1. The operations were performed at the Surgical Clinic of Mannheim (Heidelberg University) between October 1972 and April 1987. There were 172 men and 113 women. The age of these patients ranged from 23 to 75 years with a median of 53 years.

The indications for pancreatectomy in two thirds of all operations were for adenocarcinoma of the pancreas or periampullary malignancy. The preferred procedure was the Whipple operation. Total pancreatectomy was required in only 20% of these cases for reasons of radicality.

In cases where severe and complicated chronic pancreatitis was centered in the head of the pancreas, the Whipple procedure was effective in removing obstruction (of the duodenum, pancreatic, and bile ducts) and pain. Total pancreatectomy was reserved for patients with end-stage chronic pancreatitis early on in the period and has been all but abandoned for this indication since 1976. The details of our technique have been published previously.[7]

Nine patients died after operation in the hospital, for an overall mortality rate of 3.1%. The longest series of operations performed without any mortality were 75 consecutive Whipple procedures done between June 1976 and November 1981.

Although these results appear encouraging, the post-

Submitted for publication: July 7, 1987.

TABLE 1. *Early Results of Duodenopancreatectomy in 285 Patients*

Type of Procedure	No. of Patients	Diagnosis: Neoplasm	Diagnosis: Pancreatitis	Operative Hospital Mortality
Whipple operation	233	146	87	6
Total pancreatectomy	52	35	17	3
Total	285	181 (7 deaths)	104 (2 deaths)	9 (3.1%)

operative course has not been smooth all the way. On the contrary, Table 2 shows that a total of 92 complications occurred of which 42 required relaparotomy. These complications will now be analysed in detail.

Nonsurgical Complications

There were 26 major nonsurgical complications, which are listed in Table 3. These mainly concerned pulmonary, cardiac, and hepatic problems. The latter consisted solely of transient laboratory findings (elevated transaminate levels) in jaundiced patients. In this series of 285 pancreatectomies there was not one case of postoperative renal failure or so-called hepatorenal syndrome.

The one death from bronchopneumonia occurred on the 14th postoperative day in a 49-year-old man who had total gastrectomy as well as total pancreatectomy performed for a gastric carcinoma infiltrating the pancreas. The cause of death was probably aspiration pneumonia since the abdominal findings at autopsy were normal. One 75-year-old man died of myocardial infarction after an uneventful total pancreatectomy for cancer. Another patient died of venous catheter sepsis 12 days after total pancreatectomy for end-stage chronic pancreatitis.

TABLE 2. *Complications after 285 Partial and Total Pancreatectomies*

	Whipple Operation (N = 233)	Total Pancreatectomy (N = 52)
Complications (N = 92)	72 (32%)	20 (40%)
Relaparotomies (N = 42)	38 (17%)	4 (8%)
Deaths (N = 9)	6 (2.7%)	3 (6%)

Venous catheter sepsis	1	1
Total	26	3

Surgical Complications

There were 66 surgical complications, two thirds of which required reoperation. The list (Table 4) is headed both in number and severity by complications at or around the pancreatic anastomosis, followed by bleeding problems and biliary leaks. Abscesses and some more esoteric complications: chylous ascites, perforation, and jejunal torsion, conclude this list, which now will be discussed in detail.

Complications Concerning the Pancreatic Anastomosis

The group of complications feared most is that concerned with the pancreatic remnant or its anastomosis after the Whipple operation. In 233 anastomoses there were 25 complications (11%) and one fifth of these were fatal (Table 5). There was a manifest leak in 11 cases. However, with the abdomen open at relaparotomy it is not always easy to distinguish this from severe pancreatitis in the pancreatic remnant. Such an acute postoperative pancreatitis occurred 11 times.

Three bland pancreatic fistulae closed spontaneously after 2–3 weeks. The experience from two American centers (the Lahey and Mayo Clinics) with this complication are very similar: in a total of 403 Whipple procedures there were 34 pancreatic leaks (8%) with 9 fatalities (26%).[8,9]

Diagnosis. The key to successful treatment of these complications is early diagnosis. The simple clinical

findings elicited by continuous observation on the surgical intensive care unit that provide first clues are: a beginning abdominal tenderness where there was none before; the tongue slightly drier than usual; a rise in temperature, pulse or respiratory rate; oliguria and a barely perceptible agitation. Laboratory findings (leukocyte count, serum amylase, creatinine levels, etc.) invariably lag behind these subtle clinical signs. The same applies to modern imaging procedures including ultrasound and CT scans performed routinely 1 week after operation.

Case 1

A 58-year-old adipose and jaundiced patient had a Whipple procedure performed for a papillary carcinoma. Ten days later he was restless and had a slight rise in temperature and beginning epigastric rigidity. The CT scan showed an edematous pancreas and ultrasound confirmed the presence of subfascial fluid collection (Fig. 1). It was tempting just to aspirate this percutaneously. However, the clinical signs indicated something deeper and more serious, and relying on them we found a small anastomotic leak with severe pancreatitis. Removal of the remaining pancreas (total pancreatectomy) led to the recovery of this patient.

Case 2

A 60-year-old man had a palliative biliary bypass (choledochoduodenostomy) performed elsewhere for obstructive jaundice due to carcinoma of the pancreatic head. Four weeks later we performed a Whipple procedure (including portal vein resection with a mesentericocaval anastomosis). On the second postoperative day, he had tachycardia, a dry tongue, and epigastric tenderness. The tube placed to splint the biliary anastomosis then began to drain blood. At laparotomy the pancreatic anastomosis was intact. However, the jejunal loop draining it was distended and the pancreatic remnant had the mottled appearance of pancreatitis (Fig. 2). The explanation for this complication was a spurting bleeder, which we found on the cut surface of the pancreas. Due to a kink in the draining jejunal loop and a large obturating blood clot in that same loop, the blood had no free run-off. The resulting back pressure probably induced the pancreatitis. Again, the solution was a total pancreatectomy and the patient recovered.

TABLE 5. *Complications Occurring at or around 233 Pancreatojejunostomies*

Complication	N	No. of Deaths
Anastomotic leak	11	4
Acute pancreatitis	11	1
Pancreatic fistula	3	—
Total	25	5

In cases with a Völker drain splinting the biliary anastomosis, a leak may be demonstrated directly by injecting contrast medium into this drainage tube with the patient lying on his left side. But here again, it is the clinical signs rather than the radiologic findings of a leak that favor reintervention.

Case 3

A 47-year-old man had a Whipple operation for a distal common duct carcinoma. One week later a routine x-ray with contrast medium

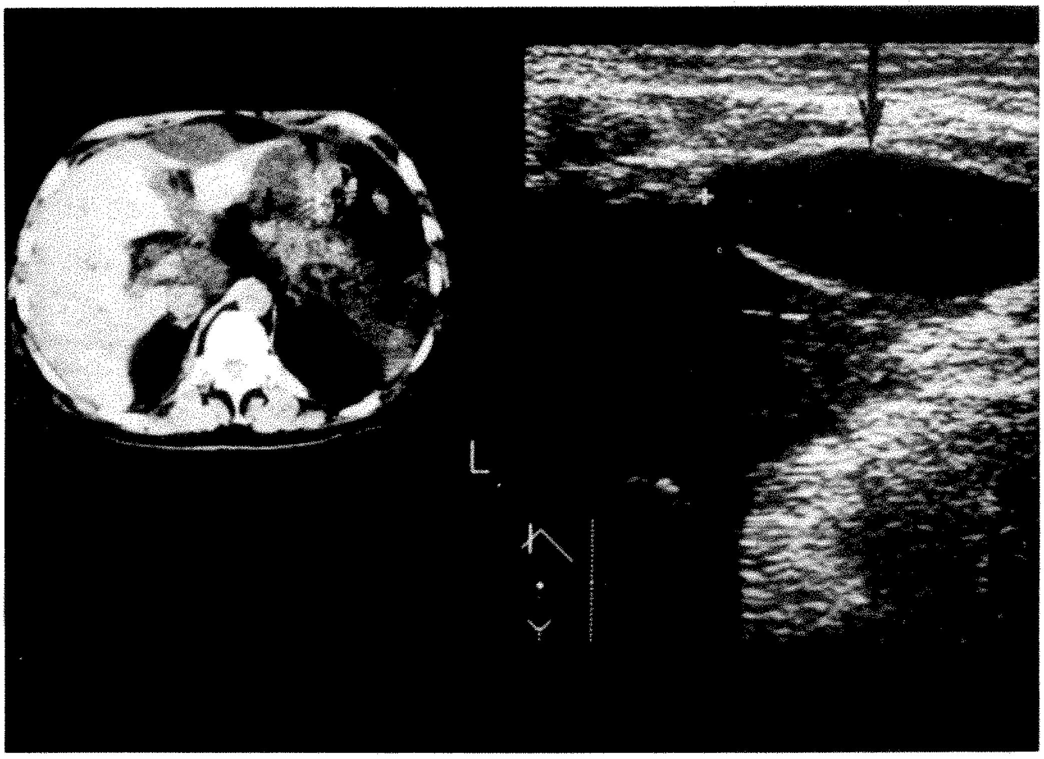

FIG. 1. *Left.* CT 10 days after Whipple procedure. Arrows point at edematous pancreatic remnant. *Right.* Ultrasound of same patient demonstrates subfascial fluid collection.

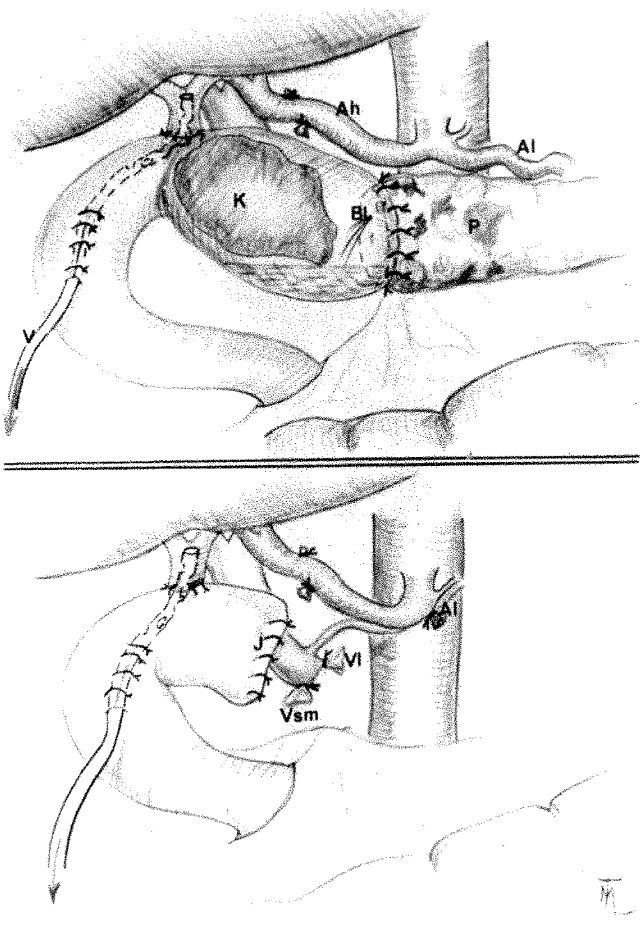

FIG. 2. *Top.* Diagram showing site of operation 2 days after Whipple procedure. injected *via* the transjejunal tube splinting the biliary anastomosis showed a leak at the pancreaticojejunostomy (Fig. 3). The normal clinical state of this patient permitted expectant treatment, and further control x-rays demonstrated spontaneous closure of this fistula without any intervention.

Treatment. Table 6 summarizes our treatment for these 25 pancreatic complications. In eight cases treatment was entirely conservative. This group includes three patients with a radiologically proven fistula. However, in these patients the clinical course was bland and spontaneous closure of the leaks followed in 2–3 weeks (Fig. 3).

In five of 11 patients the diagnosis of postoperative acute pancreatitis rested mainly on laboratory tests (*i.e.*, rise in serum amylase level). The first of these (in fact the first complication in this series) was misjudged by us: the patient died 11 days after pancreaticoduodenectomy before it became clear that her acute respiratory distress syndrome was secondary to acute pancreatitis. This experience led us to follow the rule of early reintervention when in doubt. As a consequence, two patients were reoperated on for unusual postoperative pain, who then proved to have intact anastomoses and no abdominal pathology at all. At least these "unnecessary" relaparotomies did no harm.

In a group of five patients, treatment was confined to lavage and drainage. Twice the leak had not yet led to any significant peritonitis or pancreatitis. These were both successfully treated by a combination of measures (Fig. 4): the pancreatic duct was occluded with Ethibloc and sutured, the jejunum was oversewn, and an irrigation and suction tube was placed to drain the pancreatic stump.

The very poor condition of three patients did not permit anything more than renewed drainage to be done. Only one of these patients survived.

There were 12 patients in whom the radical solution, namely total pancreatectomy, seemed unavoidable. Two patients died of uncontrollable erosive hemorrhage. However, in 10 of 12 patients, total removal of the remaining pancreas was life-saving.

Prevention. There have been many ingenious suggestions for the prevention of these complications at or around the pancreatic anastomosis. So far there only has been one certain prophylaxis: that is to avoid it altogether by doing a total pancreatectomy whenever the pancreatic remnant is very friable and the duct narrow.[10]

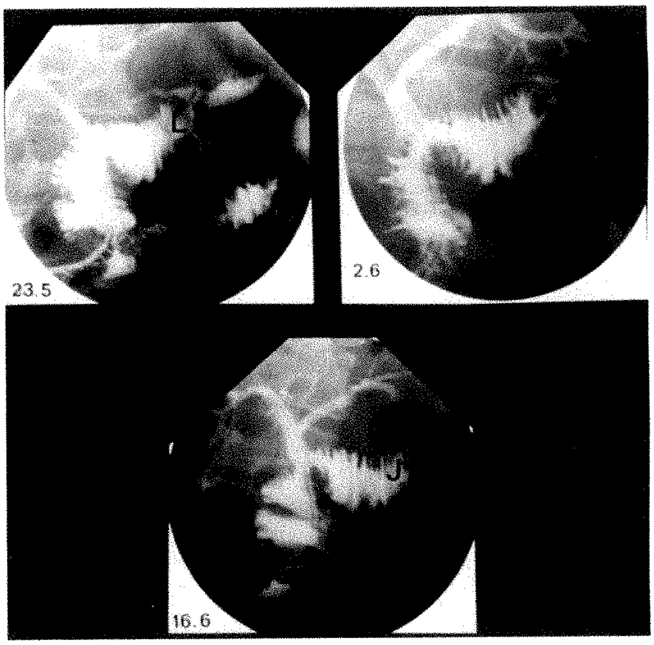

FIG. 3. X-ray with contrast medium injected through tube splinting the hepaticojejunostomy. L = leak of contrast medium through the pancreaticojejunostomy; J = the anastomosis has healed 24 days later.

TABLE 6. *Treatment of 25 Postoperative Pancreatic Complications*

		Treatment			
Complication	N	Conservative	Drainage	Total Pancreatectomy	No. of Deaths
Anastomotic leak	11	—	5 (2 deaths)	6 (2 deaths)	4
Acute pancreatitis	11	5 (1 death)	—	6	1
Pancreatic fistula	3	3	—	—	—
Total	25	8 (1 death)	5	12 (2 deaths)	5

All variations of the standard end-to-end telescope pancreaticojejunostomy have not produced better results. It does not seem to matter if additional cover is given by jejunoplication,[11] whether the pancreas is buried within the stomach wall,[12] whether three separate loops of gut are used for the gastric, biliary, and pancreatic anastomoses,[13] and whether the pancreatic duct is drained,[14] ligated, occluded, or oversewn, or all three.[15] Even doing nothing to the pancreatic remnant except for leaving a drain in its vicinity has been attempted.[16] That leaves us with the truism that in the end only a meticulous and standardized technique will lower the rate of this complication. And, once it has occurred, only its speedy detection and treatment by early reintervention can save the patient.

Postoperative Hemorrhage

Postoperative bleeding was the second common complication occurring in 16 patients (5.6%), requiring relaparotomy in 12 and ending fatally in one (Table 7).

Hemorrhage arose within the gastrointestinal tract in 12 cases, mostly from the gastroenterostomy and never from an acute stress ulcer. The presence of a day-and-night endoscopy service is invaluable here. Immediate gastroscopy can locate the site of bleeding and was successful in stopping it by laser or injection therapy in four cases.

In all but one of the remaining eight patients, relaparotomy and an additional suture stopped the bleeding. This fatality was partly due to our too-conservative approach: the oozing from the gastrojejunal suture line did not appear to be serious and endoscopic therapy was successful at first; the patient rebled, aspirated, and relaparotomy came too late. Four patients (not counting those with anastomotic leaks) bled from one of the large retroperitoneal vessels. In each patient, timely relaparotomy and suture successfully stopped the hemorrhage.

Case 4

A 61-year-old adipose and jaundiced man had a Whipple resection performed for pancreatic carcinoma. Ten days later, total pancreatectomy was done because of a acute pancreatitis in the remnant. He recovered from both operations and was discharged home three weeks later. However, he was readmitted 6 days later with pyrexia and repeated vomiting of small amounts of blood. The endoscopist located the site of the bleeding by threading the endoscope into the proximal jejunal loop; a trickle of blood was seen clearly coming from the sutured jejunal stump (Fig. 5, *top*).

At laparotomy we found a pulsating false aneurysm at this point, possibly emanating from the eroded stump of the splenic artery (Fig. 5, *bottom*). High clamping of the aorta, exposure of the aneurysm, and suture of the leak stopped the bleeding, and the patient was discharged 12 days later.

In the American experience (Lahey and Mayo Clinics) there were a total of 54 hemorrhagic complications after 403 pancreaticoduodenectomies (13%) in which 27 ended fatally.[8,9] Routine stress ulcer prophylaxis, prompt endoscopic diagnosis, and early revision, if necessary, can save most of these patients.

The role of vagotomy in the prevention of bleeding in patients who have a pancreatectomy is controversial. The ulcerogenic potential of partial or total pancreatectomy has prompted some clinics to recommend prophylactic truncal vagotomy for all of these patients.[17,18] In our experience anastomotic ulcers have not been a problem even on late follow-up, and a prophylactic va-

Biliary Fistula

Biliary leaks after partial or total pancreatectomy are rare and relatively harmless in our experience (Table 8). We came across eight such instances of 285 patients at risk (3%) and all survived. The Lahey and Mayo Clinics reported on 46 biliary fistulae with four deaths after 441 pancreatectomies.[8,9]

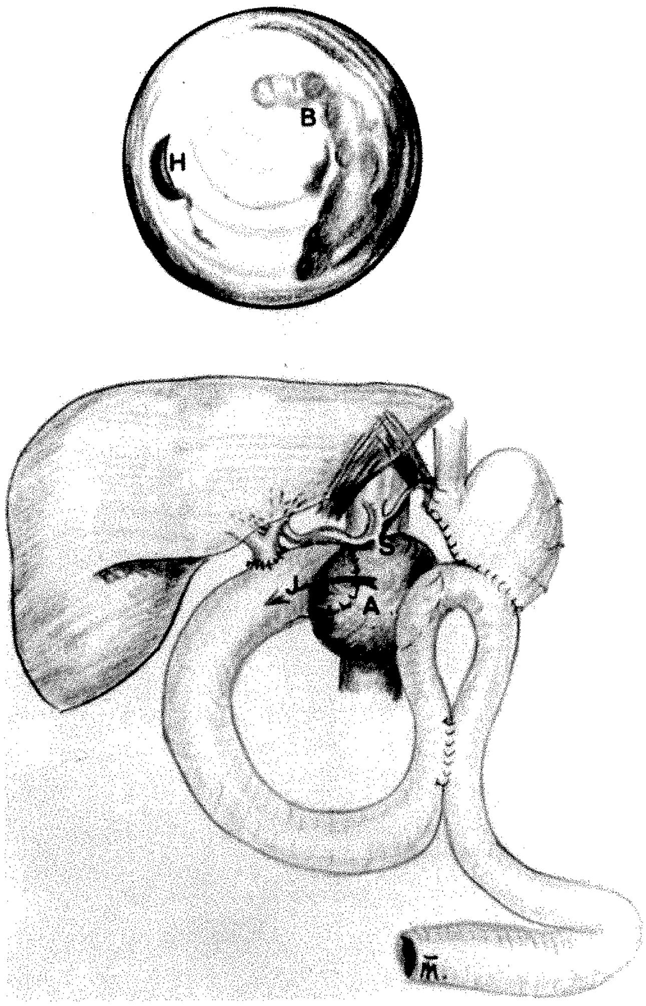

FIG. 5. *Top.* Diagram of endoscopic view into the proximal jejunal stump following total pancreatectomy. H = opening of hepaticojejunostomy draining bile; B = blood clot and fresh blood entering the jejunal stump. *Bottom.* Diagram of situation following total pancreatectomy with false aneurysm (A), arising from ligated splenic artery (S), and penetrating into the jejunal stump (J).

True anastomotic leaks occurred in four cases, two of which required renewed drainage. The other two fistulae sealed off spontaneously. Twice the bile leaked due to dislocation of the Völker drainage tube, used to splint the biliary anastomosis (Fig. 6). Removal of this drain solved the problem. Currently we use such splints only if the bile duct is narrow (less than 10 mm in diameter).

Leakage from an accessory bile duct, overlooked at the first operation, required a new anastomosis in one case only.

Miscellaneous Complications

Abscess. Seven genuine abscesses either hepatic or intra-abdominal were readily located by means of ultrasound or CT (Fig. 7). Percutaneous drainage under ultrasound guidance was possible in three of these cases; the remainder required operative drainage (Table 4).

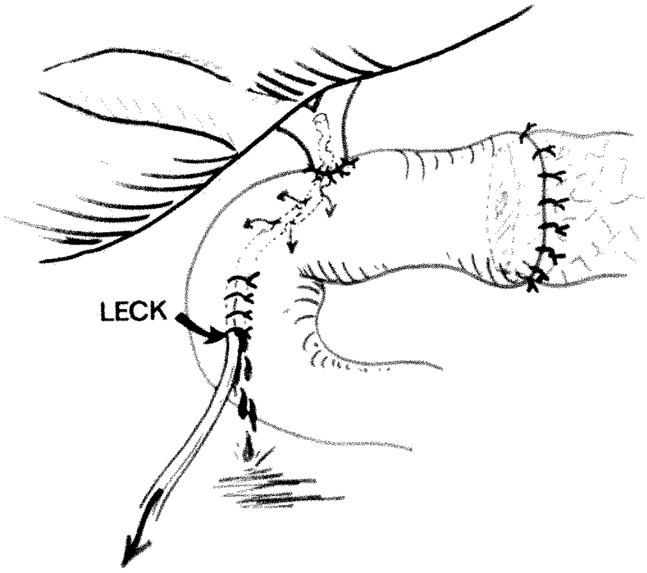

FIG. 6. Diagram demonstrating leakage of bile from the site of exit of the Völker drain.

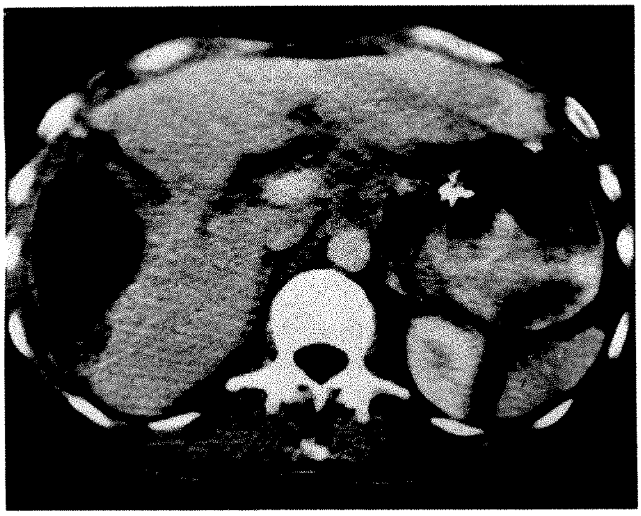

FIG. 7. CT demonstrating hepatic abscess after a Whipple procedure.

Chylous ascites. Chylous ascites occurs relatively rarely considering the extensive lymph node dissection that occurs with every pancreatectomy for cancer.[21] It can reach alarming proportions of several liters per day even requiring parenteral nutritional support. In each of our 6 cases secretion ceased spontaneously within 1 or 2 weeks.

Gastrointestinal fistula. Leakage of the gastrojejunal anastomosis, reported to occur in around 2% of cases,[8] was not seen in this series. However, one gastric perforation occurred high on the greater curvature of the stomach 7 days after total pancreatectomy with splenectomy. The cause was a small area of necrosis following ligature of the short gastric vessels. After this experience, we always secure the greater curvature with a row of Lembert sutures after total pancreatectomy.

Gastrointestinal necrosis. The following case report describes this curious complication.

Case 5

A 57-year-old jaundiced man had a carcinoma of the pancreatic head removed by a Whipple operation. After an uneventful course he had a fever, brief epigastric pain, and dyspnea on the seventh postoperative day. Since the patient seemed to improve spontaneously, we were inclined to blame this brief episode on a mild basal pneumonia, particularly since a chest x-ray seemed to confirm this.

On the next day a routine CT control showed some curiously dilated loops of bowel in the upper abdomen (Fig. 8). When the patient had another spike of temperature (39 C), we decided to reoperate. The proximal jejunal loop draining the pancreatic remnant and bile duct was grotesquely dilated and ischemic due to torsion at the Braun jejunostomy. Again there was no choice but to convert the Whipple into a total pancreatectomy and to bring up the next loop of jejunum for a new biliary anastomosis (Fig. 9).

This case emphasized once more that postoperative respiratory distress only rarely is primarily of pulmonary origin (even if x-ray evidence seems to support this

view). The real cause lies below the diaphragm in the operative field.

Discussion

On analysing these 92 complications after 285 pancreatectomies, one begins by looking for risk factors that might have caused them. Of all the nonsurgical factors studied (age, preoperative nutritional state, weight loss, etc.) only jaundice was of significance.

Of the 41 patients who had the two most prevalent and serious complications, a pancreatic leak or hemorrhage, 35 (85%) had obstructive jaundice before operation (Table 9). Five of the six deaths that occurred after these two major complications occurred in jaundiced patients. Is it worthwhile then to relieve this obstructive jaundice before operation? Three recent prospective trials addressed to this problem seem to show that this is not so.[22-24] The results summarized in Table 10 show that neither morbidity nor mortality were lowered by preoperative biliary drainage; in fact, this drainage had a morbidity of its own. However, in all three trials, drainage was performed by the rather unsatisfactory percutaneous transhepatic route. Furthermore, the bile was drained to the outside instead of into the gut where it belongs.

TABLE 10. *The Value of Preoperative Biliary Drainage (PTD) on Postoperative Morbidity and Mortality as Studied in Three Prospective Trials*

	Morbidity		Mortality

Hatfield (1982)[22]	14%	15%	14%	15%
McPherson (1984)[23]	33%	42%	32%	19%
Pitt (1985)[24]	46%	53%	8%	5%

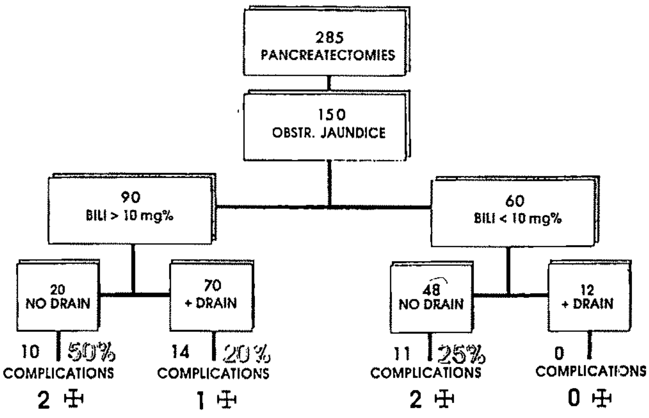

FIG. 10. Morbidity and mortality after pancreatectomy (partial and total) in a 150 patients with obstructive jaundice. Irrespective of the severity of jaundice (90 patients with bilirubin levels above, and 60 with bilirubin levels below 10 mg%), those drained before operation had less postoperative morbidity and mortality.

The analysis of our own jaundiced patients who had pancreatectomy seems to show a favorable effect of drainage by endoscopic transpapillary intubation, *i.e.*, into the duodenum (Fig. 10). There is no doubt that those patients who had drainage before operation did much better regarding complications and mortality irrespective of the severity of the obstructive jaundice.[25] However, this study was retrospective and not randomized. Perhaps the discrepancy between the results as shown in Table 10 can be explained by the different methods of biliary drainage used and by the fact that in obstructive jaundice the recovery of hepatic functions depends on many factors: the intensity and preoperative duration of jaundice and the length of the decompression. As Koyama and co-workers showed, it takes at least 4–6 weeks of decompression before hepatic mitochondrial functions return to normal.[26] This is probably longer than is feasible in cancer patients. For these reasons, we believe that the discussion on this question of preoperative decompression is not yet closed. Until it is, we will drain all jaundiced patients, if this can be done easily, at the time of the initial endoscopic cholangiography.[27] We have in so far revised our position, which used to favor one-stage pancreatectomy even in severely jaundiced patients.[25]

An additional risk factor possibly responsible for impaired healing of the pancreatic anastomosis is ischemia due to celiac artery occlusion.[28] With routine preoperative angiography one encounters few cases with such an occlusion and perfusion of the hepatic and splenic arteries *via* pancreatoduodenal arcades. The unavoidable division of these vessels during a Whipple procedure could theoretically cause ischemia of the pancreatic remnant. In actual practice this danger is overrated since other collaterals probably come in. None of our patients with surgical complications had evidence of celiac occlusion on routine preoperative angiography. Conversely, in our six patients with such a vascular obstruction, occlusion of the gastroduodenal artery did not measurably reduce flow in the hepatic artery nor were there any postoperative complications.

One final risk that deserves mention is the surgeon himself. It seems axiomatic that formidable operations such as partial and total pancreatectomy should be concentrated in those centers where experience can keep complications to a minimum or at least deal with them successfully should they occur.[29,30,31] Such centers all over the world are now reporting large pancreatectomy series with low morbidity and mortality rates under 5%.[11,32,33] However, the pioneer days of pancreatectomy are over, and towards the end of this century the well-trained "occasional pancreatectomist" may produce equally good results,[34] provided that he adheres to the following rules: (1) optimal preoperative preparation of the patient, including neutralization of the deleterious effects of obstructive jaundice and malnutrition as far as possible; (2) meticulous attention to detail in the performance of the operation itself; and (3) continuous, close observation of the patient in the postoperative period so as to detect complications on time.

Operative Treatment of Crohn's Ileocolitis Complicated by Ileosigmoid and Ileovesical Fistulae

WOLFGANG H. SCHRAUT, M.D., CATHY CHAPMAN, B.S., and V. SIMON ABRAHAM, M.D.

From the Department of Surgery, The University of Chicago Medical Center, Chicago, Illinois

Ileovesical and ileosigmoid fistulae were found to coexist in 22 patients with Crohn's ileocolitis. Persistent or recurrent urinary tract infection was a complaint in all cases, and 11 patients reported pneumaturia and/or fecaluria. Thus, bladder involvement was either suspected or clinically apparent in each patient. The cystogram was the best confirmatory test for the ileovesical fistula (positive in 9 of 22 patients). The coexistence of the sigmoid fistula was best diagnosed on intestinal radiographs (positive in 9 of 22 patients); there were no clinical signs of its presence. The coexistence of ileosigmoid and ileovesical fistulae was the sole indication for operation in two patients. In all others, a combination of factors required surgical therapy. An ileocolonic resection with primary intestinal anastomosis was performed in 16 patients and exteriorization was performed in six patients. The sigmoid defect was closed primarily in 16 patients and required wedge resection in the other six patients. The bladder defect was sparingly excised and closed with absorbable sutures. All patients recuperated without anastomotic leaks, bladder leaks, or persistent cystitis. This experience indicates that coexisting ileosigmoid and ileovesical fistulae may add complexity to an ileocolonic resection for Crohn's disease, but is not a difficult management problem for the gastrointestinal surgeon.

INTERNAL FISTULAE extending from the diseased intestine into any of the intra-abdominal or retroperitoneal organs and structures occur in approximately 40% of patients with ileocolonic Crohn's disease.[1,2] Usually, the development of these fistulae signals exacerbation or progression of the inflammatory process and is associated with the formation of a phlegmon or abscess, which becomes clinically evident as generalized malaise, tender abdominal masses, and the symptoms and signs of a small bowel obstruction. Often, this course is not abated completely by aggressive medical management, and surgical treatment becomes necessary. An ileovesical fistula that complicates the clinical course is found in 2–5% of patients who have operative treatment for Crohn's ileocolitis.[2–6] A concurrent ileosigmoid fistula may further complicate the clinical situation.[1,7,8]

An ileovesical fistula alone is often considered to present an urgent and sometimes difficult management problem for the gastrointestinal surgeon.[4,5] If an ileosigmoid fistula is also present, the combined problems may require special surgical expertise.

Patients

We describe our experience over the past 15 years with 22 patients who were diagnosed as having fistulous communications between the diseased ileum, the urinary bladder, and the sigmoid colon. Of these 22 patients, 15 were male and seven were female; their ages ranged from 13 to 54 years, with an average of 29 years. They had been diagnosed as having Crohn's disease from 1 to 25 years previously, with an average of 7 years. Six of the patients had undergone previous surgery related to Crohn's disease: four had had laparotomies without intestinal resections, which led to the diagnosis of the disease, and two had had ileocolonic resections. During the same time interval (15 years), we treated surgically 39 patients with an ileovesical fistula alone and 68 patients with an ileosigmoid fistula alone, both associated with Crohn's disease.

Clinical Features

All 22 patients had the ileocolonic form of Crohn's disease, with varying degrees of involvement of the ileum and colorectum; all patients had an exacerbation of their disease shortly before or coinciding with the development of the fistulae, and all had urinary tract infections. In five patients, the infection was accompanied by both pneumaturia and fecaluria, two others had

only pneumaturia, and four patients had only fecaluria. Ten patients also had a tender abdominal mass, which was associated with an intra-abdominal abscess in six patients. Seven patients had recurrent episodes of small bowel obstruction, and in 12 patients, the major concern was debility due to weight loss and pain not alleviated by aggressive medical treatment. All patients complained of bouts of diarrhea and defecatory frequency; however, these symptoms were not prevalent in those patients who were later found to have a large fistulous communication to the sigmoid colon.

Before operation, all patients received standard medical management (dietary restriction, steroids, Azulfidine®). Various antibiotics were given before operation for treatment of a urinary tract infection. Nine patients received total parenteral nutrition (TPN) and bowel rest before surgery, for 2 weeks to 6 months, for correction of malnutrition caused by the disease. Although TPN improved their condition, it did not result in closure of the fistulae.

Preoperative Evaluation

Cystography, performed in conjunction with an intravenous pyelogram on all 22 patients, indicated a vesical fistula in nine patients; in three of these patients, a fistulous tract was evident from leakage of contrast medium into an adjacent intestinal loop, and in the other six patients, either a mass defect or irregularities at the dome of the bladder were noted (Fig. 1). Eight of the 11 patients with pneumaturia and/or fecaluria had normal cystograms.

Cytoscopy was performed on 10 patients. A fistula was identified in six patients and severe generalized cystitis in one patient; inflammatory changes were seen at the dome of the bladder in the remaining three patients, suggesting the presence of an enterovesical fistula. Three patients with pneumaturia/fecaluria did not have cystoscopy, and three of those with positive findings on cystoscopy had neither pneumaturia nor fecaluria.

Both gastrointestinal radiography and proctosigmoidoscopy were performed on all 22 patients. The ileovesical fistula was detected by barium leakage into the bladder during a small bowel contrast study in only two patients. The ileosigmoid fistula was identified by barium contrast in nine patients (Fig. 2) and during proctosigmoidoscopy in three patients. In only one patient was the ileosigmoid fistula diagnosed by both tests.

Operative Treatment

The presence of an ileovesical fistula was the sole indication for operation in only two patients who had severe unrelenting cystitis. In the remaining 20 patients, laparotomy was performed because of complicating factors that coexisted with the fistulae; these included a tender abdominal mass that was unresponsive to medical management (10 patients), an abscess (6 patients), recurring small bowel obstruction (7 patients), and failure of medical treatment with steroids, antibiotics, and bowel rest (12 patients).

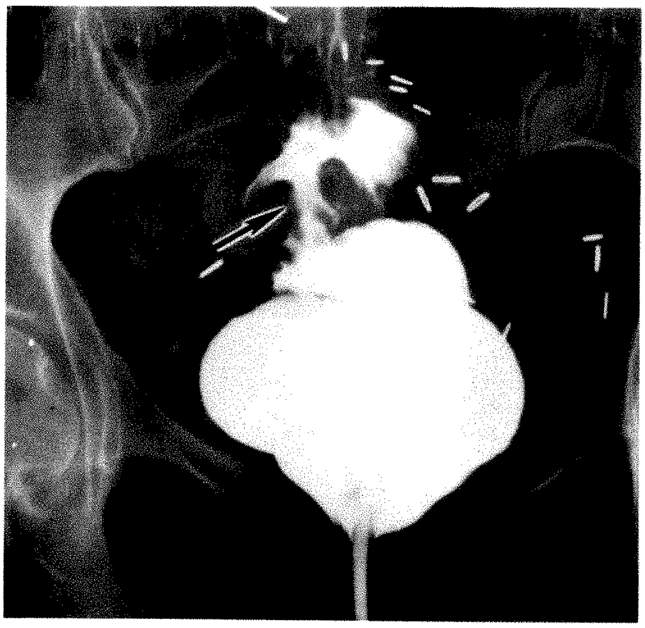

FIG. 1. The cystogram demonstrates a mass defect, mucosal irregularity, and a large fistula at the dome. The irregularity reflects mucosal inflammation and, in the presence of Crohn's disease, indicates the presence of an enterovesical fistula, even if an obvious communication with the bowel is not seen.

All patients underwent ileocolonic resection. A primary ileocolonic anastomosis was performed in 16 pa-

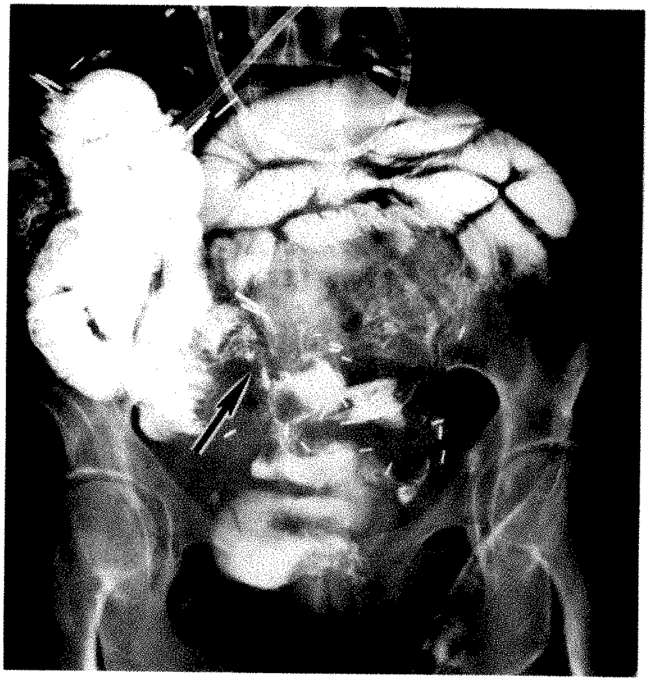

FIG. 2. The small bowel radiographic study demonstrates early sigmoid-rectal filling indicating the presence of an ileosigmoid fistula.

tients and exteriorization was performed in six patients (ileostomy, 5 patients; transverse-loop colostomy, 1 patient) who had a large intra-abdominal abscess (4 patients) and/or severe disease in the distal colon (2 patients).

In each patient, there was a single fistulous opening in the bladder that was in communication with the diseased ileum, either directly or through an abscess cavity, also giving rise to the sigmoid fistula. None of the patients had a direct sigmoid-vesical fistula separate from the ileal communication. In each patient, the dissection of the coexistent ileovesical and ileosigmoid fistulae was carried out in part bluntly by finger fracture for separation of the edematous, phlegmonous ileal and sigmoid mesentery and peritoneum at the dome of the bladder, and in part sharply for division of the actual fibrotic fistulous tracts. The bladder defect was excised sparingly or debrided and was closed with absorbable sutures; a urethral catheter was placed and remained for 1 week. The sigmoid defect was excised and closed by direct suture in 16 patients. The other six patients required a sigmoid wedge resection because they had multiple defects associated with stricture formation. The wound was closed primarily in 13 patients; delayed closure was the preferred method for the other nine patients.

Results

None of the patients had an intestinal anastomotic leak, a bladder leak, or persistent cystitis. The urine cleared within 2 days in 20 patients and within 7 days in the remaining two patients. A postoperative cystogram demonstrated that the bladder closure was intact in all patients tested.

Three patients had postoperative complications: a brachial vein thrombosis occurred in one patient, but did not require operative treatment; in another patient, an ileus developed, which resolved spontaneously; and the third patient had an intra-abdominal abscess that required operative drainage. The abscess was encountered at the dome of the bladder and extended to the left paracolic gutter. The patient had an uneventful recovery after the drainage.

Follow-up times ranged from 1 to 13 years. Crohn's ileocolitis recurred in six patients and an ileovesical fistula recurred in 1 of these 8 years after the initial resection.

Discussion

Our experience in the operative treatment of Crohn's ileocolitis includes surgery on 68 patients with an ileosigmoid[8] and 39 patients with an ileovesical fistula.[6] The review of this experience demonstrated that, if patients with Crohn's disease have an ileovesical fistula, there is a 60% probability of a concomitant sigmoid communication, and that patients with an ileosigmoid fistula have a 30% likelihood of also harboring a urinary bladder fistula. The high frequency of coexistence of these two types of fistulae in the presence of Crohn's disease must lead one to anticipate an ileosigmoid fistula once a communication with the urinary bladder is diagnosed, and *vice versa.*

An enterovesical fistula is discovered most readily on the basis of clinical findings. Dysuria was present in all of our patients, and pneumaturia and/or fecaluria was reported by 11 of the 22 patients (50%). The cystogram is the most helpful confirmatory diagnostic test. We noted that cystoscopy and intestinal radiography do not reliably indicate the presence of a vesical fistula. Such a fistula is almost always diagnosed before operation, and thus it is rarely an unsuspected intraoperative finding. An ileosigmoid fistula, however, which does not cause any specific clinical signs or symptoms, may not be detected until a laparotomy is performed. The coexistence of an ileosigmoid fistula was best diagnosed by radiographic examination, with a confirmation rate of 41% (9 of 22 patients). Conceivably, a very large ileosigmoid fistula could bypass the colon and cause rapid intestinal transit and severe diarrhea, thus indicating its presence clinically; however, diarrhea is the most common complaint of patients with Crohn's disease and certainly cannot be considered pathognomonic of an ileosigmoid fistula.

Given the frequent coexistence, one should anticipate, if not attempt to diagnose, a concomitant sigmoid communication in patients who have an ileovesical fistula. The surgeon should realize, however, that the surgical treatment of an unsuspected sigmoid fistula is not at all more demanding than that of a fistula detected before operation.

There is no specific preoperative preparation for the patient with a sigmoid fistula that would alter the intraoperative course of action or simplify the surgical procedure. Preoperative evaluation and preparation are the same for any patient undergoing an ileocolonic resection for Crohn's disease. The surgeon should determine whether the colorectum, specifically the sigmoid and rectum, is primarily involved by Crohn's disease; the presence or absence of such involvement is readily determined by proctosigmoidoscopy, which must be included routinely in the preoperative evaluation of any patient with Crohn's ileocolitis. An obvious fistulous opening often cannot be detected on proctoscopy. Frequently, however, there are localized inflammatory changes such as pseudopolyps, mucosal edema, and friability at the presumed fistula site, whereas the adjacent colonic mucosa appears normal and uninvolved.[8] In addition to endoscopic evaluation of the distal colon, radiographs of the colon and small bowel, which might demonstrate a sigmoid fistula, are necessary for diagnosis and delineation of the extent of intestinal involvement by Crohn's disease, so that a treatment program (medical management or surgical intervention) can be established for the patient.

There are no other preoperative maneuvers, tests, or treatments that would in any way influence the intraoperative approach to the repair of a sigmoid fistula or coexisting ileosigmoid and ileovesical fistulae. The major advantage in anticipating a sigmoid fistula is that the patient can be informed more specifically as to the possibility of an additional sigmoid resection or suture repair of the sigmoid defect, and that he or she can be forwarned of a possible enterostoma if the sigmoid involvement is extensive.

Often, patients with Crohn's ileocolitis and an ileosigmoid communication can be managed well without operation. Nonoperative treatment has also been suggested for the patient with an ileovesical fistula who is not troubled by other complications requiring surgical therapy. It might be that some of our patients could have been managed without operation. However, none of our patients who were stable from a medical point of view (no sepsis, no obstructive symptoms) favored continued nonoperative treatment. In all patients, the symptoms of cystitis were so severe, if not intolerable, that definitive surgical therapy was strongly indicated.

In the patient with coexisting ileosigmoid and ileovesical fistulae, one would expect that colonic as well as ileal contents will pass into the bladder. This introduction of a considerably increased quantity of bacteria into the bladder could result in increasingly severe cystitis. Consequently, early surgical intervention is indicated in the presence of a sigmoid fistula in addition to an ileovesical fistula, whereas the presence of an ileovesical fistula without sigmoid involvement and without resulting severe dysuria might not warrant instant, aggressive surgical therapy.

We found that the incidence of fecaluria and the (subjective) complaints of severe dysuria was the same for patients with an ileovesical fistula alone and patients with coexisting ileosigmoid and ileovesical fistulae. Each group included patients with severe, incapacitating dysuria and patients with lesser complaints. The degree of cystitis probably depends on the size of the communication between the bladder and gastrointestinal tract and on the degree of purulence, and not on the coexistence of a sigmoid fistula.

Conceivably, a patient who has both an ileovesical and an ileosigmoid fistula has a particularly aggressive form of Crohn's disease that favors early recurrence. Follow-up of our patients, however, has failed to indicate a higher or earlier incidence of clinically recurrent Crohn's disease. Forty-five per cent of our patients had recurrent disease, a rate similar to that reported by other centers.[9-11]

In regard to the intraoperative management of coexisting ileosigmoid and ileovesical fistulae, the surgeon may encounter difficulties in dealing with the inflammatory mass that consists of the ileocecum, the adjacent sigmoid colon, and the markedly thickened and edematous mesentery, and is attached to the urinary bladder and the retroperitoneum. This mass must be separated diligently from the retroperitoneum, but can be sharply and bluntly dissected from the bladder. The bladder defect is debrided and simply closed with absorbable sutures. Unless there is extensive involvement, the sigmoid defect can be repaired in a similar fashion; otherwise, partial resection is required. The mesentery, which is often thickened and highly vascularized and contains edematous, enlarged lymph nodes, must be transected carefully. Decisions regarding primary intestinal anastomosis and wound closure are made on the usual basis of contamination, inflammation, condition of the bowel to be anastomosed, etc.,[8] *i.e.*, according to criteria that apply to any operation on the gastrointestinal tract.

In summary, coexisting ileosigmoid and ileovesical fistulae associated with Crohn's ileocolitis is a specific complication of Crohn's disease and requires definitive surgical treatment. The intraoperative management of the ileovesical fistula does not cause undue difficulties for the surgeon, since the bladder defect is always situated at the dome. The coexistence of a sigmoid communication adds complexity to the operation, but the surgeon can deal effectively and safely with this along with the vesical component by following established surgical guidelines and practices.

Intraoperative and External Beam Irradiation for Locally Advanced Colorectal Cancer

LEONARD L. GUNDERSON, M.D., M.S.,* J. KIRK MARTIN, M.D.,† ROBERT W. BEART, M.D.,†

In view of poor local control rates obtained with standard treatment, intraoperative radiation (IORT) using electrons was combined with external beam irradiation and surgical resection, with or without 5-fluorouracil (5FU), in 51 patients with locally advanced colorectal cancer (recurrent, 36 patients; primary, 15 patients). Patients received 4500–5500 cGy (rad) of fractionated, multiple field external beam irradiation and an IORT dose of 1000–2000 cGy. Thirty of 51 patients (59%) are alive and 22 patients (43%) are free of disease. In 44 patients at risk ≥1 year, local progression within the IORT field has occurred in 1 of 44 (2%) and within the external beam field in 8 of 44 (18%). All local failures have occurred in patients with recurrence or with gross residual after partial resection, and the risk was less in patients who received 5FU during external irradiation (1 of 11, 9% *vs.* 6 of 31, 19%). The incidence of distant metastases is high in patients with recurrence, but subsequent peritoneal failures are infrequent. Acute and chronic tolerance have been acceptable, but peripheral nerve appears to be a dose-limiting structure. Randomized trials are needed to determine whether potential gains with IORT are real.

From the Departments of Radiation Oncology, Surgery,† Cancer Center Statistics,‡ and Medical Oncology,§ Mayo Clinic and Mayo Medical School, Rochester, Minnesota*

EXTERNAL BEAM IRRADIATION has been combined with surgical resection, chemotherapy, and/or immunotherapy for locally advanced colorectal cancer (unresectable for cure due to tumor fixation, residual after resection, locally recurrent). In separate series from Princess Margaret Hospital[1] and the Mayo Clinic[2] using radiation alone or with immunotherapy, local recurrence was ≥90% in evaluable patients. When radiation, with or without 5-fluorouracil (5FU), is combined with surgery for primary lesions that are initially unresectable for cure or have residual disease remaining after subtotal resection, although local control is better than that seen with no resection, the risk of local recurrence still remains too high at 30–50%.[3]

In an attempt to decrease local recurrence and improve survival with an acceptable risk of complications, our institution initiated a prospective clinical trial combining intraoperative irradiation (IORT) using an electron beam with external irradiation and section, if feasible.[3] The intent of this paper is to present our experience with the combined approaches, including IORT, in a group of 51 patients with locally advanced colorectal cancer. Our results will be compared with those achieved in other IORT trials and with alternative treatment techniques.

Methods and Materials

Patient Group

From April 1981 to February 1986, 151 patients received IORT with electrons as a supplement to external beam irradiation with or without resection at our institution. Fifty-one patients had locally advanced adenocarcinoma of the colorectum (primary, 15; recurrent, 36). Disease category of the 51 patients at the time of presentation for irradiation is seen in Table 1. The site of initial colorectal lesion was the rectum in 39 patients (recurrent, 29), the sigmoid in six patients (recurrent, 3), and the extrapelvic colon in six patients (recurrent, 4).

General criteria for patient selection and preoperative evaluation have been detailed previously.[4–7] Patients

with documented distant metastases are not usually candidates for IORT in our institution, since life span is not adequate to evaluate treatment-related effectiveness or toxicity. Two of the 51 patients in this series, however, had surgical resection of a solitary liver metastasis in conjunction with gross total or subtotal resection of their locally recurrent lesion.

Treatment Factors

The method of external beam radiation has been consistent in this group of patients. Doses of 4500–5500 cGy (rad)* were delivered in 180 cGy fractions, 5 days per week in 5–6 weeks. For pelvic lesions, treatments were given with linear accelerators using 10-mv photons and four field-shaped external beam techniques described previously.[8,9] With extrapelvic lesions, unresected or residual disease plus 5-cm margins of normal tissue were included to 4500 cGy with parallel opposed fields; reduced fields with 2–3 cm margins were treated to 5000–5500 cGy. As noted in Table 2, 49 of 51 patients (96%) completed all planned external irradiation. When used in conjunction with external irradiation, 5FU was given 500 mg/m^2 intravenous push for 3 consecutive days, week 1 and, if tolerable, week 5.

The sequence of surgery and external radiation is seen in Table 2. In the initial portion of the series, major resections were not performed after high-dose preoperative irradiation; therefore, patients had either low-dose preoperative irradiation (500 × 1, 2 patients; 1000/5 fractions, 2 patients; other, 1 patient) or none. Planned high-dose preoperative irradiation (5000–5500 cGy in 180 cGy fractions) was delivered before an attempt at surgical resection in 18 patients who had clinical disease fixation to unresectable structures that was confirmed by an abdominal pelvic CT. Subsequent gross total or subtotal resection was performed in four of four patients with primary presentation and in 13 of 14 patients with recurrence. The extent of resection before or after external irradiation and amount of residual disease by group is as follows: (1) primary: complete or gross total resection with microscopic residual [res(m)] in eight patients, partial resection with gross residual [res(g)] in seven patients; (2) recurrent: res(m) in 11 patients, res(g) in 23 patients, no resection in two patients.

Standard treatment is supplemental by IORT at the joint discretion of the surgeon and radiation oncologist. When high-dose preoperative irradiation precedes an attempt at resection, disease extent is reevaluated 3.5 to 4 weeks after completion of irradiation. If distant metastasis is not confirmed, resection is attempted in a hospital operating room. The radiation oncologist joins the surgeon at that procedure to help determine feasibility of a subsequent IORT boost and size and shape of the IORT cylinder. After abdominoperineal resection, optimal IORT field exposure is determined with regard to an abdominal *versus* perineal approach, and prone *versus* supine or lithotomy patient position.[6,7] If surgical exploration precedes external irradiation and residual or unresectable disease remains after an attempt at resection, a similar intraoperative assessment for IORT is performed.

TABLE 1. *Patient Group: Disease Category, Colorectal*

* Resected after planned high-dose preoperative RT 4 of 4 and 13 of 14 patients, an additional recurrent patient was not resected.

† Low-dose preoperative RT in 5 of 21 patients (see Table 2).

Patients selected for IORT have a secondary re-exploration in an operating room in the Radiation Oncology Department, preferably in 1–2 days, but occasionally as late as 10 days.[4] The area at risk is re-exposed and the patient is transferred within a sterile corridor to the linear accelerator room where the IORT boost is delivered.

The IORT dose is calculated at the 90% isodose line and is dependent on the amount of disease remaining after attempts at resection: res(m), 1000 cGy; res(g) ≤2 cm in largest dimension, 1500 cGy; unresected or res(g) >2 cm, 1750–2000 cGy. IORT characteristics are seen in Table 3. Electron energy varied from 9 to 18 MeV with the lower energies of 9 and 12 MeV used after gross total resection or with residual disease of minimal thickness. The 15 and 18 MeV energies and doses of

† Presacrum and pelvic sidewall could be within a single IORT field. Organ frequency within an IORT field: bladder in 7; ureter in 14; rectum in 1.

2000 cGy were used more commonly in patients with recurrent disease in whom gross residual more frequently existed after attempts at resection.

The size and shape of the lucite cylinders (cones) used for IORT are dependent on location of the IORT field. For all pelvic locations, circular cones with 15° or 30° bevels were used to conform to the anatomy of the presacrum, pelvic sidewall, or anterior pelvis. With the 30° bevel cones, the depth of the isodose curves is more shallow at the heel end of the cone than the toe end,[10] which may affect the placement of the treatment cone relative to the tumor bed or residual tumor. For extra pelvic lesions, rectangular and eliptical cones with flat or 20° bevel ends were most frequently used.

Fifty-five IORT fields were treated in 51 patients (abutting fields were used in 2 patients, and separate areas were treated in an additional 2). In three other patients, a shrinking-field technique was used to deliver 1000–1250 rad with a large cone to the area of gross total removal but narrow or microscopically positive margins, and a smaller cone was used to encompass an area of gross residual for an additional 500–1000 rad (total dose within second IORT field of 1750 in 1 patient, 2000 in 2 patients). Potential dose-limiting organs within an IORT field were the bladder in seven patients, the rectum in one patient, and the ureter in 14 patients. Nerve and vessel are usually within pelvic sidewall or presacral fields.

Results

Survival and Disease Status

Survival and disease status are shown in Table 4. Of the 15 patients who had primary disease, 10 (67%) are alive and eight (53%) are disease free (range: 10–64 months with 7 patients ≥15 months). One of five patients who died was disease free at autopsy. In the 36 patients who had recurrence, 20 (56%) are alive and 14 (39%) are free of disease progression (range: 8–50 months with 12 patients ≥12 months and 6 patients ≥2 years). One of 16 patients who died had no evidence of tumor progression. In two patients with disease progression, solitary liver metastases were resected before IORT.

TABLE 4. *Survival and Disease Status: Colorectal IORT*

		Alive		Dead	
Disease Category	No. of Patients at Risk	NED # (%)	Failure # (%)	NED # (%)	DoD # (%)
Primary	15				
Resected, residual	11	5 (45)	1 (9)	1 (9)	4 (36)
Unresectable for cure					
Resected after XRT	4	3	1	0	0
Recurrent	36				
Resected, residual	21	7 (33)	2 (10)†	4 (19)	8 (38)
Unresectable for cure	15	7 (47)	4 (27)	0	4 (27)†
Resected after XRT	13	7	3	0	3
Never resected	2	0	1	0	1
Total	51	22 (43)	8 (16)	5 (10)	16 (31)

† One patient in each group had solitary liver metastasis resected before IORT.

NED = no evidence of disease progression.

DoD = dead of disease.

XRT = external irradiation.

Kaplan-Meier survival curves are shown in Figures 1 and 2. The 4-year actuarial survival rate (Fig. 1A) is 53% in patients who had primary disease and 23% in those with recurrence. When five patients who died with no evidence of disease were censored at time of death, the survival rates are 57% and 28%, respectively (Fig. 1B). The association of treatment sequence to survival is demonstrated in Figure 2. Since only four patients with primary disease presentation received high-dose preoperative external irradiation, the current separation in survival curves should be interpreted with caution.

Incidence and Patterns of Failure

Incidence and patterns of failure were evaluated in detail. In the total group, 24 of 51 patients (47%) have evidence of disease progression (primary 6 of 15, 40%; recurrent 8 of 36, 50%). Central failure (CF) within the IORT boost field has been documented in only one patient (2% of patients at risk or 4% of failures) and local failure (LF) within the external beam field in eight patients (2 of 15 primary, 13%; 6 of 36 recurrent, 17%). Distant metastasis has occurred in 18 patients (4 of 15 primary, 27%; 14 of 36 recurrent, 39%). Peritoneal seeding has been documented in only four patients (8%) with an equivalent risk in primary and recurrent disease presentation.

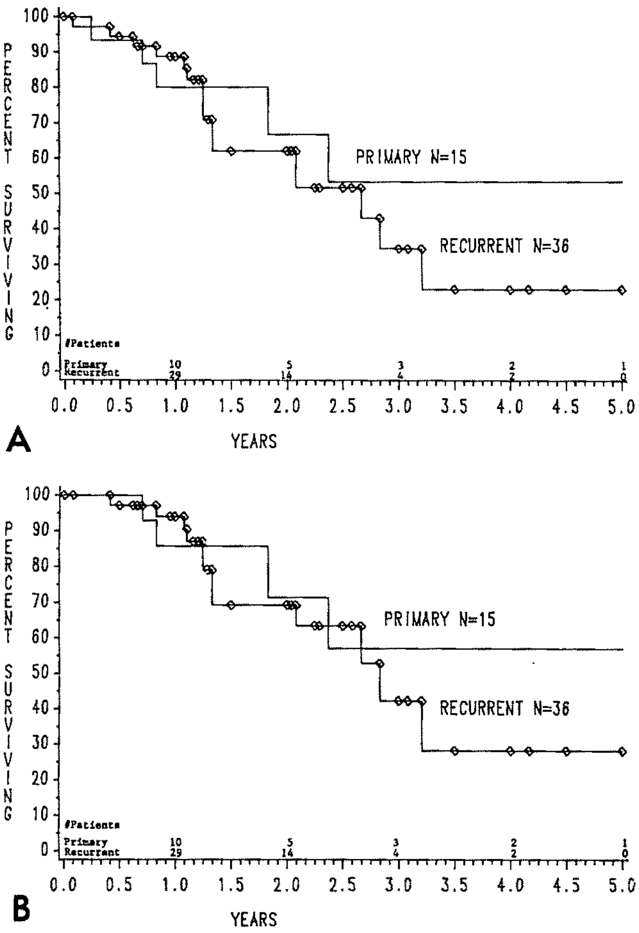

FIG. 1A and B. Kaplan-Meier survival curves for locally advanced colorectal cancer treated with IORT and external beam irradiation with 5FU. *A*. Uncensored. *B*. Censored for death with no disease. # of patients = # alive at interval.

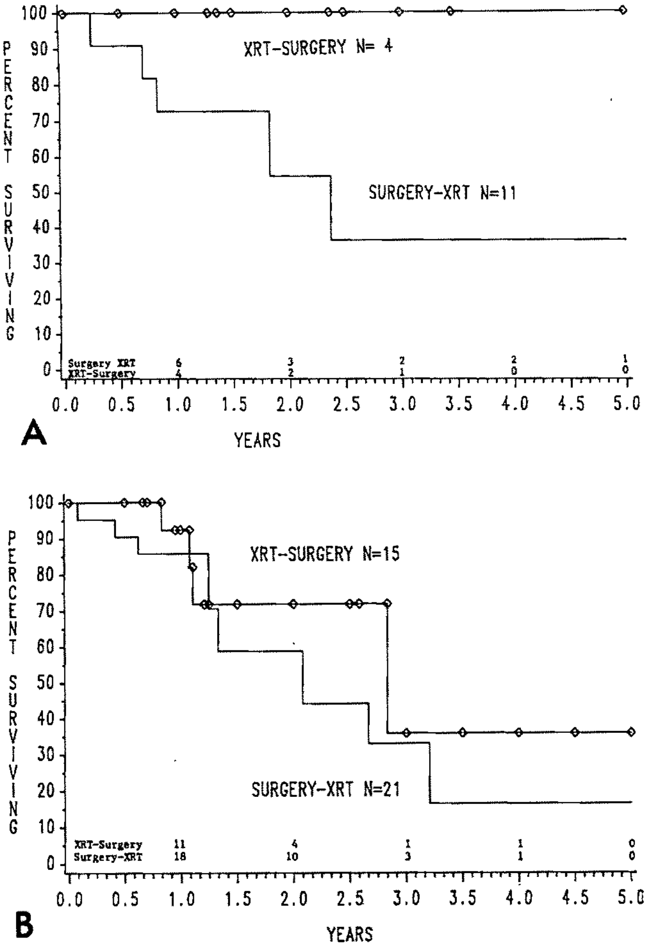

FIG. 2A and B. Kaplan-Meier survival curves with regard to sequence of surgery and irradiation. *A*. Primary disease. *B*. Recurrent.

Patients at risk less than 1 year were excluded from detailed failure analyses in Tables 5–7. The incidence of both total and distant failure remains higher in recurrent *versus* primary disease (Table 5). The impact of resection on local failure (within external irradiation field) and total failure is seen in Table 6. There was a trend for a decrease in the total failure incidence with gross total resection *versus* partial resection *versus* unresected (5 of 13, 38%; 13 of 26, 50%; 2 of 2, 100%). As shown in Table 7, the local failure incidence was lower in patients who received 5FU during external irradiation (1 of 11, 9% *vs.* 6 of 31, 19%).

Complications

An indepth analysis of complications seen in patients with pelvic IORT at our institution is the subject of

TABLE 5. *Incidence and Patterns of Failure: Colorectal IORT*

another report (E. Shaw, et al. Am Radium Society Proceedings 1987, unpublished observations). Morbidity related to nerve (Table 8) and ureter were of the most interest and will be summarized here. Symptomatic or objective neuropathy occurred in 12 of 37 (32%) pelvic IORT patients at risk ≥12 months. This was manifested as pain in all 12 patients (resolved in 5 and severe in 3), sensory in eight patients (none were severe), and motor in seven patients (resolved in 1 and only 1 severe). The IORT boost field encompassed 12 ureters in the 37 patients. Nine ureters were unobstructed before IORT, and subsequent hydronephrosis developed in four (44%). Three ureters were initially obstructed by tumor, and hydronephrosis resolved in two.

Discussion

In the United States IORT trials, some of the most favorable results have been obtained in patients who have colorectal lesions that are unresectable for cure, have residual disease after resection, or have recurrent but localized disease. Although this site did not receive much emphasis in Japanese trials,[11,12] in a recent combined analysis, five of 14 patients with IORT for colon cancer were alive.[12] One patient was alive and free of disease 9 years and 8 months after treatment and one patient at 10 years despite retroperitoneal invasion and unresected nodal disease in both.[11] The two largest reported colorectal IORT analyses are the current series and previous data from Massachusetts General Hospital.[6,7,13] Potential improvements in local control and survival with aggressive combined treatment approaches, including IORT, are most evident when compared with results achieved with previous or current "standard approaches," *i.e.*, primary irradiation combined with chemotherapy or immunotherapy or external beam irradiation combined with total or subtotal resection.

TABLE 6. *Impact of Resection on Local and Total Failure: Colorectal IORT**

	Primary				Recurrent

* 10 patients excluded from analysis. Seven at risk <1 year; two with solitary liver metastases resected prior to IORT (subsequent DM, PS); one who received only 2520 rad/14 fractions external because of previous 4000 rad (subsequent LF & DM).

LF = local failure in external beam field.

DM = Distant metastasis.

PS = Peritoneal seeding.

Total = total failures, any pattern.

Primary Irradiation

With locally advanced primary or recurrent colorectal lesions, external radiation has been shown to have good palliative and occasional curative value. With primary lesions, Wang and Schulz[14] reported long-term survival in 12.5% (2 of 16) patients who were inoperable (medical or surgical). Good or excellent palliation is obtained in approximately 75% of patients with recurrence, but the long-term survival rate is $\leq 5\%$.[2,3,14–16]

Cummings et al. presented a series from the Princess Margaret Hospital[1] in which 67 patients with tumor fixation of a primary lesion were treated with radical external beam irradiation without resection. Local control was achieved in only six of 67 patients (9%), and the 5-year actuarial survival rate was 2%.

In a recent Mayo Clinic analysis, 44 patients with locally advanced rectal cancer (unresectable in 7, resected but residual in 7, locally recurrent in 30) received 5000-rad split-course pelvic irradiation with or without adjuvant immunotherapy.[2] In the 31 patients in whom site of initial tumor progression could be evaluated, 28 (90%) had local progression within the radiation field, and in 17 patients (55%), it was their only site of disease.

Resection and External Irradiation

In separate analyses from the Massachusetts General Hospital (MGH)[17] and Albert Einstein (AE),[18,19] the incidence of local failure (LF) after subtotal resection and external beam irradiation for primary lesions varied by the amount of residual disease. With microscopic residual, the incidence was 15–26% (AE, 2 of 13; MGH, 8 of 31) but with gross residual it was 50–54% (AE, 9 of 18; MGH, 13 of 24).

With primary lesions that are unresectable for cure due to tumor fixation to an unresectable structure, preoperative radiotherapy has been used in an attempt to reduce lesion size and tumor viability, allow resection, and possibly improve local control and survival.[20–22] Although resection can be achieved in 50–75% of such patients after 4500–5000 cGy given over 5–6 weeks, the incidence of local recurrence in resected patients ranged from 35–45% in series from Tufts,[21] MGH,[22] and Oregon.[20]

External Irradiation, IORT, Resection and 5FU

A combination of external irradiation and IORT allows the safe delivery of higher effective doses of irradiation than can be delivered with only external beam techniques. With external irradiation, adjacent dose-limiting organs, such as the small bowel, limits doses to 4500–5000 cGy given in 25 to 28 fractions in many patients.[8,9,15,16] Even when the small bowel can be excluded, doses within boost fields are usually not carried beyond 6000–7000 cGy. The biologic effectiveness of single-dose irradiation is considered equivalent to 2–3 times that quantity of fractionated external beam treatment.[23] In view of that, the effective dose in the intraoperative boost field when added to the 4500–5000 cGy delivered in 25 to 28 fractions with external beam techniques is 6500–8000 cGy for an IORT dose of 1000 cGy, 7500–9500 cGy with a 1500-cGy boost, and 8500–11000 cGy with a 2000-cGy IORT dose.

TABLE 7. *Incidence of Local Failure: XRT with or without 5FU**

Disease Category/ XRT Sequence	XRT + 5FU #	XRT + 5FU (%)	XRT only #	XRT only (%)
Primary

Recurrent				
Postop XRT (3/20)	0/5		3/15	(20)
Preop XRT (2/10)	1/2		1/8	(13)
Total	1/11	(9)	6/31*	(19)

* Eight patients excluded from this analysis. Seven at risk <1 year and one received only 2520/14Fx (previous 4000 rad).

Survival and disease status. In the initial MGH report of 32 patients treated with IORT combined with external irradiation,[6] survival was higher than that seen in previous MGH series of patients treated with external beam techniques with or without resection.[3,17,22] In patients with residual disease after subtotal resection of the primary lesion, although five of seven patients with IORT had gross residual, survival rates paralleled the external beam curve of patients with microscopic residual disease.[6] For patients who initially had unresectable primaries in whom external irradiation preceded resection, survival at 1 and 2 years was statistically better in 16 patients who received an IORT supplemental dose when compared with historic controls treated only with external irradiation and resection. These advantages did not appear to be due to a difference in patient selection. In an updated analysis by Tepper et al.,[13] the 4-year actuarial survival rate is 50% in IORT patients who have

TABLE 8. *Characteristics of Neuropathy: Pelvic Colorectal IORT**

Characteristic	Incidence	Severe†	Resolved

‡ One patient lost to follow-up.

primary disease and 25% in those with recurrence (the expected long-term survival rate for locally recurrent lesions is 5% when treated with standard techniques).[14-16] The poorer survival rate in the recurrent *versus* primary disease presentation is due to a higher incidence of both local and systemic failure in the recurrent group.

In the current IORT series of 51 patients, survival results parallel those achieved at MGH (Fig. 1). Thirty of 51 patients (59%) are alive, and 22 (43%) are free of disease. The actuarial survival rate at 4 years is 53% and 23% with primary *versus* recurrent disease presentation (survival rate is 57% and 28% if deaths from unrelated causes are censored). Disease progression has been documented in 56% of patients with recurrence at risk ≥1 year *versus* 42% with primary disease. In both series, overall and disease-free survival are somewhat better when irradiation precedes resection, but this may be a function of case selection.

Distant metastases (DM). In the IORT series from both institutions, systemic failure has been more common in patients when surgery preceded high-dose irradiation and with recurrent *versus* primary disease presentation. In the initial MGH series,[6] in patients with primary disease, the comparative systemic failure incidence was three of six patients (50%) when surgery preceded irradiation *versus* two of 16 patients (13%) when the sequence was reversed. That trend is also seen in the current series in patients at risk ≥1 year (DM in 11 of 27 or 41% when surgery preceded irradiation *vs.* 5 of 15 or 33%). Whether the lower incidence is due to a different treatment sequence (*i.e.,* preoperative irradiation may alter implantability of cells spread at time of resection) or is due to case selection cannot be ascertained, as choice in treatment sequence was not controlled in either series. The incidence of DM in the current series is 44% *versus* 33% for recurrent *versus* primary lesions.

Local control. Most local regrowths in the MGH IORT series[6,13] and all in the current series have been in patients who had recurrent lesions or gross residual after partial resection of primary lesions. In the initial MGH report, local control appeared to be improved in both the patients with residual disease and initially unresectable disease who received an IORT boost[6] *versus* those who received only external beam irradiation.[17,22] In their updated analysis,[13] local control at 4 years is 85% *versus* 30% for primary *versus* recurrent disease with a definite advantage in patients with gross total resection (≤ microscopic residual) *versus* partial resection or unresected disease. In the current series, the addition of 5FU during external irradiation resulted in a possible decrease in the risk of local recurrence (1 of 11 patients or 9% with 5FU, 6 of 31 patients or 19% with radiation alone). An improvement in local control with radiation plus chemotherapy *versus* radiation alone has also been seen in two randomized adjuvant rectal trials.[24-26]

Morbidity. In patients with locally advanced colorectal malignancies, it is difficult to place the question of morbidity after treatment into clear perspective. If external radiation is used as the main treatment modality, ≥90% of patients had local persistence or recurrence of disease in analyses from the Princess Margaret Hospital and the Mayo Clinic and most were dead at 3–5 years (end result is nearly 100% morbidity). If aggressive surgery with pelvic exenteration or distal sacrectomy is performed alone or in conjunction with external irradiation, significant morbidity ensues even if the tumor is controlled.[16]

With combinations of external irradiation, surgery, and IORT (with or without 5FU), subsequent problems with healing or infection could be related to the advanced stage of tumor growth or regrowth (10 of the initial 32 MGH patients and 36 of the 51 Mayo patients had recurrence), the difficulty of the surgical resection or reresection, and aggressive radiation. A significant increase in soft tissue complications has not been encountered in the MGH series of patients who received an IORT boost in comparison to patients with similar disease extent treated with external beam irradiation alone.[27] Some problems with delayed wound healing have been encountered in IORT patients in whom an infection in the pelvis or a perineal wound developed after preoperative irradiation and abdominoperineal resection.[4,6,7] Neither the magnitude nor the incidence of such problems was increased when compared with patients treated with only preoperative irradiation and resection at MGH[22,27] or at other institutions.

Problems with delayed pelvic pain or paresthesias have been reported in series from both institutions, and motor difficulties have also been discussed in the current analysis. It is uncertain whether these findings are a result of irradiation fibrosis with nerve entrapment, direct neuropathy, or a combination of both. The incidence in the current series is higher than from MGH and is probably a function of a larger percentage of patients presenting with recurrent disease (with pre-existent pain and nerve damage) and the use of higher IORT doses (in the initial 32 MGH patients, the highest IORT dose was 1500 cGy and in the current series the IORT dose exceeded 1500 cGy in 28 of 51 patients). Motor deficits have been rare in contrast to a recent report from NCI.[28] None were reported in the MGH analyses and there was only one case of severe magnitude in the current series.

The finding of ureteral narrowing with IORT plus external irradiation is not surprising in view of animal studies from NCI[29,30] and Colorado State University.[31] In the current series, four of nine (44%) previously unobstructed ureters became partially or totally obstructed when included in the IORT field, and hydronephrosis resolved in two of three that were obstructed by tumor. If tumor is adjacent or adherant to the ureter and is uncontrolled, ureteral obstruction occurs in nearly 100% of patients. Our policy, therefore, is to include the ureter within the IORT field in the presence of tumor adherence or involvement.

Conclusions and Future Possibilities

The long-term results of an aggressive treatment approach for locally advanced malignancies are dependent on disease presentation (primary *vs.* recurrent), on the metastatic potential of the lesion, and possibly on the sequencing of external irradiation and resection. Distant failures in the MGH and Mayo IORT colorectal series were most common in patients with recurrent disease or who had partial resection of primary disease before moderate dose external irradiation. With both primary and recurrent disease, it may be preferable to deliver the external irradiation before attempted resection and IORT boost (deliver 4500–5000 cGy in 25 to 28 fractions; restage approximately 4 weeks later, do partial or gross total removal, and give IORT boost if feasible). Theoretical advantages of this sequence include: (1) potential alteration of implantability of cells, which may be disseminated at the time of partial surgical resection (spread of cells is more likely in patients with gross transection of tumor); (2) deletion of patients with metastases detected at the restaging workup or at laparotomy, thus sparing the potential risks of an IORT boost; and (3) reduction of the treatment interval between external and intraoperative radiation. If the resection and IORT boost are the initial phase of treatment and the patient has postoperative complications, the interval to the start of external irradiation may be prolonged to the degree that the combined IORT plus external doses do not have an additive antitumor effect but only an additive effect on normal structures (*i.e.*, added risk but no potential gain).

Since similar encouraging trends exist in separate colorectal IORT analyses from MGH and Mayo, expansion or refinement of IORT approaches seem warranted. Such combined treatment programs appear to improve local control and possibly survival of locally advanced colorectal lesions. In an attempt to further decrease the incidence of local failure, the role of radiation dose modifiers during external irradiation (5FU) or IORT (sensitizers, hyperthermia, etc.) needs to be evaluated. Treatment of the liver and/or peritoneal cavity with intraperitoneal chemotherapy or radiocolloids, infusion chemotherapy, external radiation, or combinations may be necessary in patients who have high metastatic potential. If either infusion chemotherapy of the liver[32,33] or intraperitoneal chemotherapy decreases the incidence of liver metastases in ongoing trials with colon cancer, it would be worthwhile to consider the same approach with locally advanced colorectal cancer. Even with locally recurrent lesions, the aggressive multimodality approaches have resulted in projected long-term survival rates of 25–30% *versus* an expected 5% with conventional techniques. Randomized trials will be needed that compare standard treatment to treatment that includes an IORT boost to see if previous observed differences are true advantages or are merely due to a difference in case selection.

Acknowledgments

The authors appreciate the efforts of Julie Boland and the Mayo Typing Service for assistance in the preparation of the manuscript, and to the radiation oncology physicists and technicians, OR nurses, and many additional physicians who were involved in the treatment of the patients.

Thirty-five patients who had adenocarcinoma of the middle third of the rectum were treated by resection and coloanal anastomosis. The aim of this study was to assess functional and oncologic results of an original technique of coloanal anastomosis. There was no operative mortality, and operative morbidity consisted of seven anastomotic leaks with two failures. Among 31 patients assessed for functional results only one had unsatisfactory results. Good continence was obtained within a few weeks for the 30 patients who had satisfactory results. No patients were lost to follow-up, which was over 5 years in 24 patients (68%). The 5-year survival rate was 64%, identical to that for other series.

INDICATIONS OF SPHINCTER-SAVING procedures have become more frequent for carcinomas of the middle third of the rectum since a 2-cm margin is considered sufficient for distal clearance.[1,12,29,47] Whereas the results of Babcock's operation and low anterior resections have been extensively studied, there are only a few reports about resection with coloanal anastomosis (CAA). We report a series of 35 manual CAA on the dentate line after macroscopically curative resection of invasive adenocarcinomas of the low rectum. The aims of this study are to assess the reliability of an original technique of CAA and its functional and oncologic results.

Patients and Methods

Patients

From March 1969 to June 1984, 35 patients had rectal excision with peranal CAA in our surgical unit. There were 22 men and 13 women aged 31–83 years (mean: 55 years). They all had a rectal adenocarcinoma, which had infiltrated at least the submucosa and was mobile at digital palpation. According to Dukes' classification,[7] 12 cases were graded A, 11 were graded B, and 12 were graded C1. Tumor growth was circular in 4 cases, occupied more than a quarter of the colonic circumference in 22 cases and less in nine. Distances between the distal growth margin and the anal verge are indicated in table 1. This distance was 9 cm or less in 25 cases, and between 9 and 12 in the remaining ten.

Surgical Technique

The patient was placed in the lithotomy position. A long midline laparotomy was made. The abdominal procedure used was identical to the one for abdominoperineal excision: it comprised high ligation of the inferior mesenteric artery, division of the lateral ligaments on the pelvic wall, and complete mobilization of the rectum down to the level of the levators and of the anorectal junction. The sigmoid colon was divided and closed. The perineal procedure consisted of exposing the dentate line by rectal eversion followed by CAA. It started with a gentle anal stretch and irrigation of the rectal stump with an antiseptic solution after a rectal clamp had been positioned. In cases of low and/or small tumor growth, the stump was everted with the tumor after division and closure. In cases of bulky and/or higher growth, the rectum was divided and closed below the tumor, and the lower stump everted. In all cases the distal division was made on the dentate line, which was progressively exposed by a series of stay sutures. The specimen removed was then opened to ensure that a minimum distal margin clearance of 2 cm had been preserved, in which case CAA was performed. The left colon was completely mobilized by dividing the inferior mesenteric vein at the lower margin of the pancreas; this maneuver enables the distal end of the colon to be easily

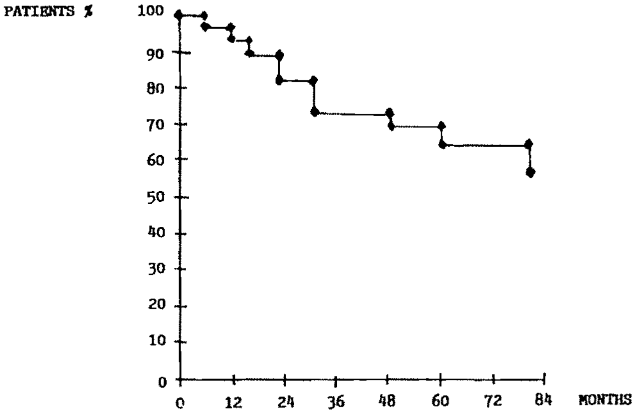

FIG. 1. Actuarial survival curve according to Kaplan-Meier.

drawn toward the anus. Anastomosis was performed manually, quadrant by quadrant, using a one-layer series of total interrupted sutures of slowly absorbable material. No anal retractor was used. The anastomosis was located on the dentate line, and after completion returned spontaneously into the pelvis, at the top of the external sphincter. A defunctioning colostomy was systematically performed, usually exteriorized in the left lower quadrant. The absence of anastomotic leak was systematically checked by contrast enema, 2 months after excision, before colostomy closure. No adjuvant therapy was used.

Assessment

All patients were assessed for continence and defecation and for local and distant oncologic recurrences. The acturial curve of survival was constructed by the method of Kaplan-Meier.[19]

Results

Mortality and Morbidity

There were no postoperative deaths, either after resection or colostomy closure. Outcome was simple and continuity restored after 2 months in 26 patients (74%). Specific morbidity consisted of anastomotic leak, which occurred in seven of the remaining nine patients (20%). Four of these leaks (11%) were symptomatic with anal suppuration but no reoperation was necessary. The three others (9%) were discovered on the routine contrast enema. In six of these seven patients, colostomy was subsequently closed with two failures (recurrent anal suppuration necessitated a second colostomy in 1 patient and the other had a persistant vaginal leak). In three of the nine patients with a complicating outcome, continuity was never restored because of an early pelvic tumor recurrence. There were no cases of colonic necroses or anastomotic stricture even in patients who had a leak.

TABLE 1. *Distal Margin According to Duke's Classification*

Dukes' Stage	Less than 6 cm	6–9 cm	9–12 cm	Total
A	5	5	2	12
B	0	9	2	11
C	0	6	6	12
Total	5	20	10	35

Functional Results

Functional results were assessed in 31 patients. They were considered unsatisfactory in one patient. In 30 patients, flatus and stool could be differentiated and retained and the need to defecate was felt. None of these patients wore pads, but minimal leaks occurred in some patients in cases of diarrhea. In the first months after colostomy closure, 50% of the patients had frequent bowel actions; 1 year later, stool frequency was 2/24 h in 27 patients and 3–6/24 h in three patients. In these 30 patients, no intubation, dilatation, diet, or medication were necessary. The one unsatisfactory result was due to a persistant vaginal leak.

Oncologic Results

No patients was lost to follow-up, which was over 5 years in 24 patients (68%). The actuarial curve of survival is shown in Figure 1. Six patients (17%) had a pelvic tumor recurrence and another patient (5%) had a recurrence on the anal canal below the anastomosis. According to Dukes' classification, initial tumor growth was classified as B in one of the seven patients and C1 in the other six patients. There was no local recurrence in the cases classified as A. The distal clearance margin was over 2 cm in all patients. It was less than 3 cm in one patient, between 3 and 5 cm in five patients, and between 5 and 7 cm in one patient. In no case did the pathologic examination of resected specimens reveal involvement of the distal margin. Five of the seven local recurrences occurred within 3 years of resection. Of the remaining two recurrences, one, which was paravaginal, occurred 6 years after resection and was treated by local excision and radiotherapy; 4 years later (June 1986) the patient is alive and free of disease. The last patient whom recurrence was infra-anastomotic was treated by curietherapy and radiotherapy; at first he refused abdominoperineal excision, but this was performed 1 year later.

Discussion

There were no postoperative deaths in our series, and the mortality rate reported after CAA in other series was always below 4%.[6,24,30] This rate is comparable with the rates for abdominoperineal excision and low anterior resection. The main postoperative complication was anastomotic leak.[11] It occurred in 20% of our patients, but was only clinically significant in 11%. In the other series of CAA, the rate of anastomotic leak ranged from 9.7 to

11.9%, but no routine radiologic examination of the anastomosis was made and only symptomatic leaks were taken into account. The rate of anastomotic leak after anterior resection was usually about 9% except for Localio et al., who reported a rate of 1%.[24,25,43,44,48,50] The risk of leak does not seem to be reduced when stapled anastomoses are performed.[10] The frequency of leak after CAA is not much higher than after low anterior resection, but we believe it justifies the systematic use of a covering colostomy, which reduces the risk of leak.[6] The covering stoma is not always used by Localio et al., who defined a high-risk group, but they reported four cases of generalized peritonitis, one of them fatal. Thus, in the current series, no leak led to peritonitis or death, and only two of the seven leaks led to permanent functional failure (5.7%).

It is not evident that a transphincteric approach facilitates resection or suture, and we believe that section of the anal sphincter is open to criticism, even when it is carefully repaired.[21,51] We believe that the advantages of our technique are good exposure of the dentate line, which facilitates suture, no stretching of the anal sphincter with a permanent retractor, and the absence of septic contamination of the pelvis.[37] The functional results of the different methods of CAA are comparable.[6,23,24,30,31,37] Satisfactory continence is usually obtained within a few weeks of colostomy closure. No case of night leak has been reported. Only one author reported the need for protection pads in 50% of his patients and flatus incontinence.[16] On the other hand, defecation disorders were reported in most series.[6,23,30,31] Patients pass several stools a day, sometimes with urgency, with variable frequency from one day to another. Occasional minor leaks are possible, especially in the case of diarrhea. In our series, as in others, functional results usually improved 1 year after surgery. This might be connected with the possible reappearance of the rectoanal inhibitory reflex, as showed by manometric studies.[42] The same type of defecation disorders are reported after very low anterior resections, especially when less than 4 cm of rectum are preserved.[2] They are due to the disappearance of the rectal reservoir. The construction of a colonic pouch combined with CAA might be useful in the early postoperative months.[22,33,46] There were no anastomotic stenoses in the current series or in most of the others. Only Keighley and Matheson reported cases of such stenosis, but with they used a rectal muscular cuff and some of these stenoses were due to pelvic tumor recurrence.[14] The general absence of stenosis is probably due to the performing of true sutured anastomosis, contrarily to Babcock's procedure, which is associated with a high rate of stenosis.[15,17,41] This is one of the major advantages of CAA *versus* Babcock's operation. The satisfactory clinical results for CAA confirm that the preservation of the levators ani and of the anal canal leads to good continence despite the absence of rectal ampulla.[3,18] In fact, the puborectalis has sensory receptors when it is stretched in addition to its motor role.[34,35] Therefore, the nerves, located on the endopelvic side of levators ani, should be preserved.[38] Furthermore, the colonic stump should be sufficiently mobile to fill the sacral concavity, thus constructing an anal angle and making contact with the levators. The occurrence of pelvic sepsis may lead to fibrosis and alter the continence.[20]

The 5-year survival rate of 64% in this series is identical to that for other series. The rates reported for anastomotic recurrence are very low (1.3–2.3%). Here, we only observed one recurrence below the anastomosis without pelvic recurrence, but no anastomotic recurrence. Our pelvic recurrence rate of 17% is comparable with that of Localio (14.6%) and Nicholls (13%). Like us, these authors did not use any complementary therapy. In several series, the results of abdominoperineal excision have been compared with those of sphincter-saving procedures in treating carcinomas of the middle third of the rectum.[25,30,43,44,48,49,50] In cases of curative resection, 5-year survival rates range from 55 to 65%, whether total excision or restorative procedure is performed. All these studies are retrospective, and their Dukes' stage distribution are not equivalent; therefore, the distribution for abdominoperineal excision is unduly pessimistic. However, prognosis seems more closely related to the tumor stage than to the type of surgical procedure.[24,30,48] In two series matched for Dukes' staging, Williams showed that there was no difference in survival or recurrence, whether middle-third lesions were treated by an abdominoperineal excision or a sphincter-saving procedure. Similar results are reported by Wilson, Localio, and McDermott.[23,25,49] In our series, there were no local or distant recurrences in the 12 patients with a Dukes' A tumor. Of the 11 patients with a Dukes B tumor, three died of cancer (2 metastases and 1 local recurrence). Three of the five deaths that occurred among the 12 patients with Dukes C1 growth were due to an isolated pelvic recurrence.

The location of the lesions treated by resection and CAA did not influence the rate of pelvic recurrence. It seems that this rate only rises when a lesion is located less than 5 cm from the anal verge.[5] Pathologic clinical studies show that the distal clearance margin can be reduced to 2 cm.[12,18,39,40,47] However, this margin should not be systematically reduced to 2 cm, as some authors believe this is insufficient in cases of poorly differentiated or Dukes' B tumors.[4,28] We believe that in lesions encroaching on the lower third of the rectum this margin is only acceptable when they are small and mobile. Intrarectal ultrasound might help preoperative staging of wall extension.[13] In cases of bulky and higher growths, CAA allows a wider margin of clearance than low anterior anastomosis. In resection of middle-third and some lower-third rectal carcinomas, sphincter and pelvic floor saving seems possible without increasing the risk of local recurrence. Finally, it is difficult to compare the results of CAA with those of other sphincter-saving procedures (transanal excision, electrocoagulation, and irradiation) for which pathologic staging is not available.[7,32,45]

Colorectal Villous and Tubulovillous Adenomas Equal to or Greater than Four Centimeters

JAROSLAV P. STULC, M.D., NICHOLAS J. PETRELLI, M.D., LEMUEL HERRERA, M.D., AND ARNOLD MITTELMAN, M.D.

From the Roswell Park Memorial Institute, Department of Surgical Oncology, Buffalo, New York

The records of 237 patients treated for benign and malignant villous and tubulovillous adenomas at Roswell Park Memorial Institute from 1963 to 1987 were reviewed. Sixty-five adenomas were ≥4 cm and form the basis of this report. Fifteen (23%) were in the cecum, 3 (5%) in the right colon, 1 (1%) in the splenic flexure, 10 (15%) in the sigmoid colon, and 36 (55%) in the rectum. The most common symptoms were rectal bleeding (70%), mucus diarrhea (44%), constipation (22%), and tenesmus (19%). Fifty-five (85%) of these large adenomas contained invasive adenocarcinoma and one in situ carcinoma. Two thirds of invasive carcinomas arose from predominantly villous adenomas and one third from tubulovillous adenomas. Half of all malignant adenomas demonstrated metastases to regional lymph nodes or distant metastases. Seven malignant adenomas (12%) were associated with synchronous adenocarcinomas of the colon, and 29% of malignant adenomas were associated with synchronous adenomatous polyps, principally tubular type. Four of nine benign, large adenomas were associated with synchronous adenomas but with no adenocarcinomas. No relationship was found between the size of the adenoma, location, or Dukes' stage. Though the incidence of in situ and invasive carcinomas is clearly related to the size of the adenoma, a linear relationship could not be demonstrated.

ADENOMAS of the colon and rectum represent true neoplastic growths and are generally regarded as potentially premalignant lesions. Villous and tubulovillous adenomas together constitute from 19–53% of colorectal adenomas.[1–3] The villous component has been implicated as the determinant more likely to be associated with in situ and invasive adenocarcinoma.[2–9] The other determinant has been directly related to size, with a proportionate increase in invasive carcinoma in larger lesions.[2,3,9–11] However, adenomas with a villous component are recognized for their ability to attain large dimensions without incurring concomitant malignancy, and invasive carcinoma is not uncommonly found in villous or tubulovillous adenomas <2 cm in size.[2,3,7,9–11] Given the uncertainty of malignant involvement in an adenoma, particularly of the larger lesions, various clinical and histologic criteria have been reported concerning polypectomy *versus* surgical resection.[7,12–16] Earlier reviews have advocated a conservative approach toward management of villous adenomas, even in the presence of invasive carcinoma, based on the contention that these lesions demonstrated a benign course with little predilection for metastases.[10,11,17]

Studies to date on colorectal adenomas have not discriminantly looked at large adenomas with a villous component; conversely, since the inception of the colonoscopy era, the literature has focused primarily on adenomas that can be removed by virtue of colonoscopy alone, often with the exclusion of malignant lesions.

The purpose of this review is to examine the clinical nature of villous and tubulovillous adenomas ≥4 cm in diameter and to correlate this with location of the lesions, incidences of in situ and invasive adenocarcinoma, and Dukes' staging.

Materials and Methods

This retrospective study reviews the medical records of 237 patients with villous or tubulovillous adenomas of the colon and rectum treated at Roswell Park Memorial Institute from 1963 to 1987. Only those patients with histologically confirmed benign and malignant villous and tubulovillous adenomas were included. Pa-

tients with papillary adenocarcinoma, polypoid adenocarcinoma, and equivocal histologic diagnoses were excluded. By these criteria, six patients were excluded from the study, and of the remaining 231 patients, 63 patients (27%) had villous or tubulovillous adenomas ≥4 cm. Two patients each had two synchronous villous lesions greater than 4 cm in diameter, constituting a total of 65 villous tumors. There were 28 women and 35 men with a median age of 66 years (range: 45–82 years).

Dimensions of the villous tumors were measured along their greatest diameter. Direct measurements of the surgical specimen were available in all instances, and if this was at variance with measurements obtained on colonoscopy, the more conservative measurement was used. All tumors resected at Roswell Park Memorial Institute were subjected to lymph node clearance using alcohol extraction of fat and fixation of lymph nodes in cedar oil.[18] Pathologic staging was performed according to the Gastrointestinal Tumor Study Group (GITSG) as follows: Dukes' A: mucosal invasion; Dukes' B_1: tumor through mucosa but no serosal penetration; Dukes B_2: serosal penetration; Dukes' B_3: serosal penetration with direct involvement of adjacent organs; Dukes' C_1: 1–4 lymph nodes positive for tumor; Dukes' C_2: more than 4 positive lymph nodes; Dukes' C_3: involvement of adjacent organ and positive lymph nodes; and Dukes' D: distant metastases. Patients were analyzed according to the site of primary villous tumor, frequency of benign *versus* malignant adenoma, pathologic stage in regards to site of the primary lesion and size, and site of the tumor in relation to size.

Results

Of 65 total villous tumors, 55 (85%) were found to contain invasive adenocarcinoma, defined as invasion through the muscularis mucosa, and one tumor (1%) contained *in situ* adenocarcinoma. The remaining nine (14%) villous tumors contained no foci of carcinoma. Twenty-one villous tumors were diagnosed prior to 1973 by barium enema and proctosigmoidoscopy, of which only two adenomas were found to be benign. Forty-four additional villous tumors were diagnosed after 1973, principally by colonoscopy, and 37 of these contained adenocarcinoma. The location of the primary villous tumors was as follows: cecum, 15 (23%): 13 contained carcinoma and two were benign; ascending colon, three (5%): two contained carcinoma and one was benign; splenic flexure, one was benign; sigmoid, 10 (15%): eight contained carcinoma and two were benign; rectum, 36 (55%): 33 contained carcinoma and three were benign.

Though the number of villous tumors of the rectum diagnosed prior to and after the institution of colonoscopy were similar (16 and 20, respectively), three malignant villous adenomas of the right colon and one of the sigmoid were diagnosed prior to 1973, while 12 malignant villous adenomas of the right colon and seven of the sigmoid were diagnosed subsequent to the introduction of colonoscopy.

Fifty-six villous or tubulovillous adenomas contained carcinoma. In each case, clear demarcation or transition from benign villous or tubulovillous component to *in situ* or invasive carcinoma was apparent on histologic examination. Since all carcinomas arose either centrally or along one border of the adenoma, measurements were based on the extent of the grossly benign component. The adenocarcinomas were as follows: one Dukes' A, 13 Dukes' B_1, ten Dukes' B_2, one Dukes' B_3, 14 Dukes' C_1, one Dukes' C_2, 2 Dukes' C_3, and ten Dukes' D carcinomas (Table 1). In four additional rectal villous adenomas with invasive carcinoma, Dukes' staging was not possible because three patients refused abdominoperineal resection following transanal or transsacral resection of the villous adenoma, and one patient underwent transanal resection of a malignant villous adenoma in conjunction with right hemicolectomy for a synchronous cecal adenocarcinoma. Of 15 malignant villous adenomas of the cecum and right colon, 66% were metastatic to lymph nodes, and of 29 staged malignant villous adenomas of the rectum, 50% were metastatic to lymph nodes (Table 1).

Differentiation of the 55 villous adenomas with invasive carcinoma was as follows: well differentiated, 27; moderately well differentiated, 26; poorly differentiated, 2; and one *in situ* adenocarcinoma. The degree of differentiation of the tumor bore no relation to the site or size of the primary.

Clinically, the most frequent symptoms were rectal bleeding (44 patients) and a change in bowel habits (38 patients), with mucus diarrhea being twice as frequent as constipation. Eight patients experienced tenesmus, six patients experienced vague, crampy abdominal pain, six noted weight loss, one noted a decrease in stool caliber, and one had prolapse of a rectal tumor. Two patients presented with anemia and six patients were asymptomatic with a lesion found either on routine examination of the lower gastrointestinal tract or by fecal occult blood. No patients experienced the syndrome of voluminous diarrhea and hypokalemia. The range of duration of symptoms was from 1 month to 8 years, with a median of 7 months.

Fifty-nine patients underwent 64 procedures for excision or resection of their villous tumor (Table 2). Two patients with metastatic disease underwent colonoscopy only and biopsies of the tumor, and one large villous adenoma was found incidentally at autopsy. Seven patients (12%) had synchronous invasive adenocarcinomas of the colon that did not arise in association with an adenoma. A total of 40 synchronous adenomas of the colon and rectum were found in 16 of the 56 patients (29%) with malignant villous adenomas. The majority of these adenomas were tubular, and of these, one patient had six tubular adenomas of varying size concomitantly with two synchronous malignant, large villous adenomas. Two patients had tubulovillous adenomas containing invasive carcinomas. The remaining polyps were an even distribution of tubular, villous, and mixed tubulovillous adenomas, with the majority containing *in situ* carcinomas. Three of 9 (33%) benign, large villous adenomas were associated with a total of 22 synchronous benign adenomas. One patient harbored 16 tubular adenomas in association with a benign cecal villous adenoma.

In contrast to the adenomas synchronous with malignant, large villous adenomas, the adenomas synchronous with benign, large villous adenomas were in no instance found to contain either *in situ* or invasive adenocarcinomas. Furthermore, in both benign and malignant villous adenomas, the associated adenomas were principally located in the same segment of colon or rectum with the primary villous adenoma.

TABLE 2. *Surgical Procedures for Villous and Tubulovillous Adenomas**

Procedure	Number of Villous Adenomas Without Carcinoma	Number of Villous Adenomas With Carcinoma	Total
Exploratory laparotomy	0	1	1

Fulguration†	0	2	2
Polypectomy	1	3	4

* Two patients with metastatic carcinoma (rectal and cecal adenoma) underwent colonoscopy and biopsies of the primary lesion only; one patient had the adenoma found incidentally at the time of autopsy.

† One patient subsequently underwent abdominoperineal resection, and the other patient underwent subsequent low anterior resection.

In regards to metachronous adenocarcinoma of the colon, two patients with malignant villous adenomas of the rectum subsequently developed adenocarcinomas of the right colon within several years, and one patient with a malignant cecal villous adenoma developed adenocarcinoma of the transverse colon 18 months following resection of the first primary. Three patients with malignant villous adenomas of the cecum had previously undergone resection of sigmoid adenocarcinomas. Follow-up concerning metachronous adenomas, however, has not been sufficient to allow for significant data.

The size of the villous and tubulovillous adenomas ranged from 4–20 cm. Four malignant villous adenomas (two cecal and two rectal) were annular but exceeded 4 cm in diameter longitudinally. For benign and malignant villous and tubulovillous adenomas, the mean diameters were 5 cm. The site of the adenoma had no correlation with its size (Tables 3 and 4). When the

TABLE 3. *Size (cm) of Villous Adenomas Without Carcinoma Related to Bowel Site*

Rectum	5.5	12	10	2	3	3	0	1	1

Dukes' stage of malignant villous adenomas was compared to the mean size, no correlation was found (Table 5). In four malignant adenomas of indeterminable Dukes' stage, mean diameter was 5.5 cm, and one villous adenoma with *in situ* carcinoma was 5 cm in diameter. Thirteen Dukes' B_1 tumors had a mean diameter of 7.6 cm, but this included two large villous adenomas of 14 and 20 cm, respectively. Ten Dukes' B_2 carcinomas had a mean diameter of 5.8 cm; one Dukes' B_3 tumor was 10 cm, one Dukes' C_2 carcinoma was 5 cm, two Dukes' C_3 tumors were 6 cm, and ten Dukes' stage D adenocarcinomas were 5.4 cm in mean diameter. Therefore, the size that a villous adenoma can attain does not appear to be significantly modified by its location in the colon or rectum. Similarly, the presence or absence of malignancy and the pathologic stage of a malignant villous adenoma clearly are not related to location of the primary adenoma nor to its size (Tables 3–5).

Discussion

Adenomas of the colon and rectum are generally regarded as premalignant lesions. Morphologically, adenomas are differentiated as either tubular, villous (papillary), or tubulovillous (villoglandular or mixed). The villous component was initially recognized as a distinct clinical entity with a significant potential for malignant transformation; the incidence of malignancy was directly proportional to size and degree of villous component.[19,20] Following the introduction of colonoscopy in 1973, the relationship between colorectal adenomas to the development of malignancy was conceptually developed.[1–11]

Though fiberoptic endoscopy is the preferred approach to the management of colonic polyps, particularly those that are pedunculated, the majority of villous and a significant number of tubulovillous adenomas are sessile. The endoscopic removal of larger sessile polyps entails increased morbidity and the increasing probability of incomplete resection with possible residual disease left behind. On the other hand, risk may outweigh benefit if the patient is subjected to a formal surgical procedure under circumstances in which there is a reasonable chance for benign disease.

Several large series have attempted to delineate criteria for further surgical intervention in adenomas with invasive carcinoma. The retrospective series by Wolff and Shinya[2] analyzed 892 endoscopically resected polyps, of which 57.3% were tubular adenomas, 29.2% were tubulovillous adenomas, and 12.4% were villous adenomas. Conversely, invasive cancer was most prevalent in villous adenomas (12.6%) followed by tubulovillous adenomas (3.8%) and tubular adenomas (3.3%). Invasive carcinomas were most frequent in larger and sessile lesions. This is a sanction confirmed by a later study by Shinya and Wolff[3] demonstrating that all gradations of cellular change from dysplasia to invasive carcinoma increased in all colon segments as the villous component of the adenoma increased. In the same series, when the villous adenoma was ≥3 cm in diameter, the incidence of carcinoma *in situ* was 33% *versus* 21.4% in tubulovillous adenomas. The incidence of in-

vasive carcinoma was 13% *versus* 15%, respectively. Though polyp size was an important determinant for the presence of malignancy, invasive cancer was also found in polyps <1 cm in diameter. Furthermore, it has been recognized that adenomas with a predominantly villous component can attain large dimensions without developing invasive carcinoma.

Due to the fact that no previous studies had discriminately analyzed large colorectal adenomas with a predominantly villous morphology (greater than 60% of morphology), our study was undertaken. Based on the literature citing a significant increase in the frequency of carcinoma in villous adenomas >3–4 cm in diameter, an arbitrary lower limit of 4 cm was chosen. Of the 237 histologically documented villous and tubulovillous adenomas of the colon and rectum in a 24-year period extending from 1963 to 1987 at Roswell Park Memorial Institute, 65 cases of villous adenomas ≥4 cm were found. The incidence of invasive adenocarcinoma was found to be 85%. This is a significantly higher percentage than has been cited in the literature.[2,3,7,9,12] In comparison, Shinya and Wolff found the incidence of invasive carcinoma in villous and tubulovillous adenomas ≥3 cm to be on the order of 13–15%,[3] and Christiansen et al.[12] found a 48.5% incidence of invasive carcinoma in clinically benign villous colorectal adenomas >2 cm in diameter.[12] Muto et al.[7] reported a 46% incidence of invasive carcinoma in tubular and villous adenomas >2 cm. An incidence of invasive carcinoma of 32% was found in villous and tubulovillous adenomas >4 cm in diameter in a series of 1049 patients by Galandiuk et al.[9] In part, the high incidence of invasive carcinoma in our series may reflect the tertiary referral pattern of our institution. Another explanation may relate to the fact that a pathologist, when confronted with a colorectal surgical specimen obviously containing adenocarcinoma, directs attention to the confirmation of adenocarcinoma and may overlook or disclaim contiguous areas of benign adenoma. This may be particularly true in those larger lesions where the adenocarcinoma has overgrown the adenoma from which it initially arose. In small adenomas at an earlier stage of invasive carcinoma the predominant nature of the benign component and the transition into invasive carcinoma is more apparent.

The location of large villous and tubulovillous adenomas in our series was primarily in the right colon (28%) and the rectosigmoid (55%). A similar distribution of adenomas with a villous component has been reported in the literature,[2–16] though the frequency of cecal lesions was somewhat higher in our series. Approximately 50% of the malignant adenomas were located in the rectum, which is consistent with other studies.[9,10,12] The overall number of rectal adenomas diagnosed endoscopically remained the same before and after 1973, but four times as many cecal and right colon adenomas were noted following the introduction of colonoscopy. This may reflect a more accurate incidence of large villous and tubulovillous adenomas of the cecum and right colon, since these lesions classically are asymptomatic until they attain large size, can be readily missed by barium enema examination, and can be overlooked even by direct palpation or endoscopic examination.

In our series, 37 of 56 malignant adenomas were predominantly villous, 13 tubulovillous adenomas contained invasive adenocarcinoma, and three adenomas of each type contained both *in situ* and invasive carcinomas. In contrast, of the nine benign adenomas, four were predominantly villous and five were tubulovillous. The differentiation of the adenocarcinomas was evenly divided between well differentiated and moderately well differentiated, with only two poorly differentiated adenocarcinomas. Seventeen malignant villous and tubulovillous adenomas were noted to secrete large amounts of mucin. Five of these malignant adenomas were located in the right colon, one in the sigmoid, and 11 in the rectum. The Dukes' stage of mucin-secreting adenocarcinomas was uniformly distributed.

Seven of the 56 malignant adenomas (12%) had synchronous adenocarcinomas of the colon at the time of diagnosis. The incidence of malignancy is also directly proportional to the frequency of synchronous and metachronous adenomas.[3,9] In our series, 16 of 56 malignant adenomas (29%) were associated with 40 synchronous adenomas; the majority of these were tubular, with two containing invasive adenocarcinoma and seven containing carcinoma *in situ*. Interestingly, in virtually every instance, synchronous adenomas were found to be in the same segment of colon or rectum as the malignant primary adenoma.

Difficulty in assessing the presence of malignancy in larger polyps and the controversy regarding management of early invasive carcinomas in adenomas has led to the evolution of guidelines for management. Currently, the rationale for surgical intervention is predicated upon polyp size, sessile *versus* pedunculated, adequacy of margin, patient age, and the presence or absence of multiple synchronous or metachronous adenomas.[2,3] Further determinants also include the increased risk for carcinoma from 5–15 years for single adenomas and the male population older than 60 years of age.[15] Induration within a rectal villous adenoma has been suggested as a reliable clinical sign for the presence of invasive carcinoma.[13] Villous and tubulovillous adenomas in all segments of the colon and rectum and through all ranges in size have a known propensity to develop carcinoma. The morphology of these polyps is predominately sessile. In spite of this, several reports have advocated a conservative approach toward the management of large villous adenomas on the premise that they can be benign and that even if invasive carcinoma is present it is rarely metastatic and follows a relatively benign course.[10,11,17,21] This is contradicted by literature that demonstrates a 28–46% incidence of invasive carcinoma in villous adenomas >3 cm and a metastatic potential.[3,7,8,9,16] Furthermore, the biopsy failure rates for identifying invasive adenocarcinoma in a villous adenoma are 40–50%.[10,12]

The local recurrence rate for surgical excision alone of a villous adenoma of the colon and rectum is 17–30%,[10,12] all recurrences presenting within the first five years. The recurrence rate for villous adenomas that have been fulgurated is significantly higher and the time interval to recurrence significantly shorter. The local recurrence of a benign villous adenoma has been associated with a 7.7% incidence of subsequent malignancy.[11] However, there is a trend among endoscopists to treat villous lesions of the colon and rectum that cannot be totally removed endoscopically with electrocoagulation or laser coagulation, thus not only increasing the likelihood of local recurrence but increasing the chances of failing to recognize invasive carcinoma.

In our series of 52 malignant villous adenomas in which the Dukes' stage was determined, over 50% of the malignant villous adenomas had metastasized to regional lymph nodes or were associated with distant metastases. Half of all metastases were to visceral organs without associated lymph node involvement, raising the possibility that invasive carcinomas arising within villous adenomas do not metastasize primarily via lymphatics. For invasive carcinomas arising in rectal adenomas, seven of 32 carcinomas recurred locally within the rectovaginal septum or within the true pelvis, and another three had extension to bladder, prostate, or pelvic wall at the time of initial exploration and resection.

We speculated that although tubular and villous adenomas represent variations in an otherwise general abnormal cellular change, villous adenomas carry a higher potential for malignancy that may be biologically predetermined at an early stage in the induction and growth of the polyp. Noting that *in situ* and invasive adenocarcinomas occur in villous adenomas irrespective of size, and that some villous adenomas attain very large sizes without incurring malignancy, it is conceivable that foci of *in situ* carcinoma arise early in these polyps and are recognizable and predetermined by the time the polyp reaches a size from of 1–2 cm. This is further supported by observations that invasive carcinomas within an adenoma were confined in our series to one focus and that the coexistence of several areas of invasive carcinoma within the same large villous or tubulovillous adenoma was never observed, even after careful histologic examination of serial sections. Furthermore, the coexistence of separate foci of *in situ* carcinoma in adenomas with invasive carcinoma was infrequent. There is, of course, the possibility that separate foci of invasive carcinoma rapidly coalesce and overtake the more indolent growth of the accompanying benign component. Further studies involving careful sectioning of all adenomas with *in situ* and invasive carcinoma to determine the incidence of concomitant malignant foci would be required.

Nevertheless, it is unlikely that villous and tubulovillous adenomas simply undergo malignant transformation beyond a certain critical dimension. The contention that all adenocarcinomas of the colon and rectum arise from preexisting adenomas is also arguable. More likely is the possibility that many colorectal adenocarcinomas either are contiguous with benign components that are not appreciated by the pathologist at the time of examination of the surgical specimen, or eventually destroy any continguous benign component. Lastly, the assumption that villous adenomas in general follow a benign course and that invasive adenocarcinomas arising within these adenomas are of low grade without significant metastatic potential is not supported by our study.

Summary

In our review of 65 villous and tubulovillous adenomas ≥4 cm in diameter, 85% demonstrated a focus of invasive adenocarcinoma. The principal locations of all adenomas were in the right colon and rectosigmid region. The most frequent site of malignant tumors was in the rectum (58%), the right colon (27%), and sigmoid colon (15%). There was no relationship between size of the adenoma, location of the adenoma, or Dukes' stage. Half of all malignant adenomas demonstrated metastases to regional lymph nodes or distant metastases. Though the incidence of invasive and *in situ* carcinomas is clearly related to size of the adenoma, a linear relationship between size and incidence of malignancy could not be demonstrated in adenomas ≥4 cm. It is therefore postulated that adenomas with a predominant villous component to their morphology are biologically predetermined at an early stage in the growth of the neoplasm to manifest cellular changes capable of leading to malignancy. Otherwise, the neoplasm retains the capacity to attain large dimensions without ever incurring malignancy.

The Management of Penetrating Injuries of the Back

A Prospective Study of 230 Patients

D. DEMETRIADES, PH.D., B. RABINOWITZ, F.R.C.S., C. SOFIANOS, M.D., D. CHARALAMBIDES, M.D.,
J. MELISSAS, M.D., C. HATZITHEOFILOU, M.D., and J. DA SILVA, M.D.

This is a prospective study of 230 patients with penetrating injuries of the back. The decision to operate or observe was taken exclusively on the abdominal physical findings. One hundred ninety-five patients (85%) did not require operation, 30 (13%) underwent a therapeutic laparotomy, four (1.7%) an unnecessary operation, and one patient (0.4%) had a completely negative laparotomy. The diagnosis and management was delayed in five (2.2%) patients with no serious consequences. Mortality rates were not recorded in this series. The initial physical examination was accurate in 95.2% of the patients. We suggest that penetrating injuries of the back should be assessed in the same way as anterior abdominal injuries. Physical abdominal examination is reliable in detecting significant intra-abdominal injuries.

From the Department of Surgery, Medical School, Johannesburg, South Africa

WE HAVE PREVIOUSLY SHOWN that many anterior abdominal penetrating injuries can safely be managed exclusively on abdominal physical examination. Evisceration, paracentesis positive for blood, free air under the diaphragms, and shock on admission are not absolute indications for surgery.[1,2] Penetrating wounds in the back are generally considered as a distinct form of abdominal trauma.[3] The vertebral column and the thick musculature provide a better protective barrier than the anterior abdominal wall, and retroperitoneal injuries may not be clinically detectable in the early stages. In the present study we report our experience with this type of trauma.

Patients and Methods

A prospective study over a 15-month period (1986–1987) took place in three of five surgical units at Baragwanath Hospital, Johannesburg. The back was defined as the area between the tips of the scapulae, the iliac crests, and both midaxillary lines. Patients with superficial wounds, as shown by digital exploration, were not included in the study.

Patients with signs of an acute abdomen (severe tenderness, guarding, or rebound tenderness) were operated on immediately. Patients with no abdominal signs or minimal ones (mild, local tenderness) were chosen for conservative management. Following physical examination (which included auscultation of the renal regions for a bruit) erect chest and abdominal x-rays were taken, and urine was tested for blood. In the presence of a bruit or gross hematuria an intravenous pyelogram (IVP) was done. A renal arteriogram was obtained if the kidney was not visualized on IVP. All patients had a nasogastric tube inserted and were put on hourly blood pressure and pulse checkings for 24 hours. The abdomen was assessed clinically every 3 to 4 hours. No prophylactic antibiotics were given, except in the presence of an intercostal drain for an associated hemopneumothorax. If signs of peritonitis developed, an operation was carried out; otherwise, the patients were discharged, usually in 2 to 3 days.

Results

There were 230 patients (202 men and 28 women) with a mean age of 26 years. Twenty-three per cent of the patients had multiple wounds in the back. The weapon was a knife in 97% of the cases, and a gun in 3%. The victims reached the hospital in a mean time of 90 minutes after the injury.

Initial Assessment

Thirty-five patients (15.2%) had signs of an acute abdomen on admission and were operated on immediately. The remaining 195 (84.8%) were selected for observation. Microscopic hematuria was present in 57 (25%) and gross hematuria in 8 (3.5%) patients. An IVP was obtained only in the 16 patients with gross or 4+ hematuria on dipstick, and abnormalities were demon-

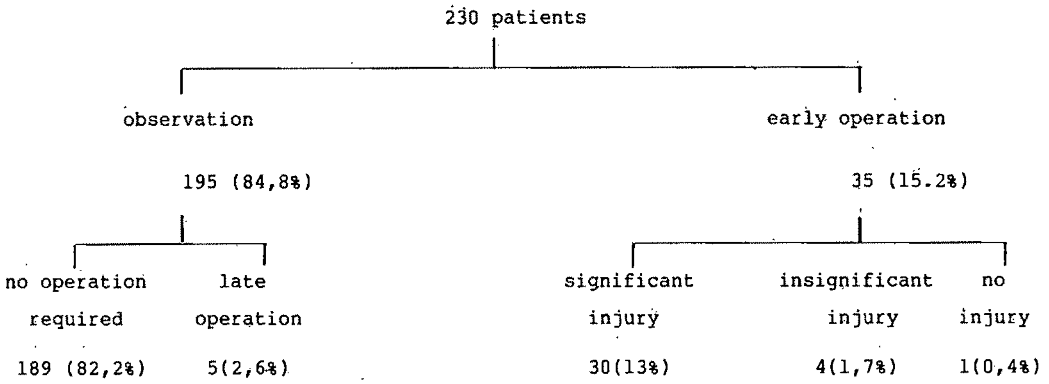

FIG. 1. Management of 230 patients.

strated in four patients. However, the IVP did not directly influence the emergency management in any of our patients. An abdominal x-ray was obtained in all patients, but it was diagnostic in only six cases (2.6%) where it showed free air under the diaphragm. Five patients had signs of an acute abdomen, and they would have been operated on irrespective of radiologic findings. The most common associated injury was a hemopneumothorax (32% of the patients) followed by a head injury (6%).

Results of Treatment (Fig. 1)

Of the 35 (15.2%) patients who were operated on immediately 30 (13%) had serious intra-abdominal injuries requiring repair, 4 (1.7%) had nonsignificant injuries (*i.e.*, retroperitoneal hematomas, small liver lacerations), and one (0.4%) had a completely negative laparotomy. The injured viscera in the patients with a positive celiotomy included nine colons, five kidneys, five diaphragms, four small bowel, two livers, two stomachs, two spleens, and one pancreas. No mortality rate or significant intra-abdominal complication was recorded in the group of patients who underwent an early operation. The average hospital stay was 7 days.

In the group of 195 (84.8%) patients who were initially selected for observation, five (2.2%) developed signs of peritonitis and were operated on, but retrospectively the operation was necessary in only four (1.7%). Another patient developed a bruit over the kidney and a false aneurysm was diagnosed on angiography. A partial nephrectomy was performed (Table 1). There was no mortality rate, but there was one pancreatic fistula that closed spontaneously. In the remaining 190 patients who were managed nonoperatively there was no mortality rate. The average hospital stay was 2.4 days. One patient was readmitted 8 weeks after discharge with a right subdiaphragmatic abscess that was drained percutaneously.

Discussion

The assessment of penetrating injuries of the back is generally considered more difficult than assessment of injuries of the anterior abdomen. The confinement of the damage to the retroperitoneum may result in delay of the diagnosis and management of a serious injury. Missed colonic or duodenal perforations may prove catastrophic. For these reasons concern has been expressed about the safety of conservative management of penetrating wounds of the back.

Routine exploration is associated with an unacceptably high incidence of unnecessary operations. The thick musculoskeletal wall of the back provides a good protective barrier to the intra-abdominal structures. In this study only 34 patients (14.8%) had a significant intra-abdominal injury requiring surgical intervention. Other series reported similar findings.[4,5] In anterior abdominal wounds this figure is 52%.[1] A negative laparotomy performed under emergency conditions, often by junior staff, poses significant risks. Because of these problems, most trauma centers apply some form of selective conservative management. Physical examination, local exploration of the wound for peritoneal penetration, peritoneal lavage, and sophisticated contrast-enhanced CT enemas have all been used to identify the patients requiring surgery.

The diagnostic accuracy of the initial abdominal physical examination has been reported to be between 72 and 92%.[3,4,6] Our experience has demonstrated reliability with an overall accuracy of 95.2% (false-positive, 2.6%; false-negative, 2.2%). We have reported similar results for anterior abdominal wounds (651 patients: overall accuracy, 94%; false-positive, 3.2%; and false-negative, 2.9%) (Table 2).[1] We attribute our high accuracy to three factors: (1) selective conservatism has been extensively used at our hospital for more than 25 years;

TABLE 1. *Five Late Operations*

Delay	Operative Findings	Complications	Hospital Stay (d)
36 h	Pancreatic injury	Fistula	25
48 h	Retroperitoneal hematoma		6
4 h	Small bowel		7
6 h	Colon (primary repair)		7
10 d	Renal aneurysm (partial nephretomy)		7

TABLE 2. *Accuracy of Physical Examination in Anterior and Posterior Abdominal Wounds*

	No. of Patients	False-positive Initial Physical Examination (%)	False-negative Initial Physical Examination (%)	Accuracy of Physical Examination (%)
Anterior abdominal wounds	651	3.2	2.9	93.9
Posterior abdominal wounds	230	2.6	2.2	95.2

* Demetriades and Rabinowitz.[1]

(2) we see large numbers of patients with penetrating trauma; and (3) experienced surgeons are always present on a 24-hour basis.

Local exploration of the wound has been used as a screening method for identifying patients requiring surgery.[6] However, exploration through the thick musculature of the back is a difficult task. Furthermore, deep penetration does not mean serious intra-abdominal injury. We have shown that 30% of the patients with proven peritoneal penetration do not have significant intra-abdominal injuries requiring surgery.[1]

Peritoneal lavage has been advocated in the assessment of these patients.[3,4,6] We believe that lavage has no place in the management of penetrating injuries of the back. If the injury is confined in the retroperitoneum, the lavage will be falsely negative. A lavage positive for blood is not an absolute indication for surgery. Free blood may have originated from the abdominal wall wound or from a superficial liver laceration. We have shown that many penetrating liver injuries can be managed nonoperatively.[7] The dangers associated with peritoneal lavage in the presence of a colonic perforation cannot be overemphasized.

Phillips et al.[4] used contrast-enhanced CT enemas to detect significant visceral or vascular injuries. The procedure includes a gastrographin meal, a gastrographin enema, and intravenous diatrizoate, combined with an abdominal CT scan. This expensive and time-consuming investigation had a yield of less than 2%, and there is no data to support that it detects small retroperitoneal perforations of the colon or duodenum. Further assessment of this technique is necessary.

The value of the plain abdominal x-ray seems to be very limited. We have a positive yield of 2.6%, and in no case did the radiologic findings directly influence the decision to operate or observe. Free air under the diaphragm is not in itself an absolute indication for operation. Although these cases are assessed with great caution, the final decision to observe or operate is taken exclusively on the abdominal physical examination. The free intraperitoneal air may have originated from outside through the abdominal wound or from an associated right pneumothorax with perforation of the right diaphragm.

We have previously reported 16 such patients treated conservatively.[1] Chest x-rays are essential in the diagnosis of a hemopneumothorax or diaphragmatic injuries. An elevated left diaphragm or suspicion of viscus in the chest should be further investigated by means of screening, contrast studies, or laparoscopy in the appropriate cases. The role of the IVP in the assessment of penetrating injuries of the back is not clear. Some authors recommend routine IVP irrespective of urinalysis.[3] Others reserve this investigation for patients with microscopic or gross hematuria. We perform IVPs only for wounds over the kidneys associated with gross hematuria or 4+ hematuria on dipstick. Coppa et al.[3] recommended exploration of all penetrating renal injuries. We reserve operative intervention only for pedicle injuries or uncontrollable hemorrhage. Any other kidney injuries are managed conservatively. Follow-up of these patients for late development of false aneurysms or arteriovenous fistule is imperative.

In conclusion, we believe that penetrating injuries of the back should be assessed in the same way as those of the anterior abdomen. Physical abdominal examination is reliable in detecting significant intra-abdominal injuries. There is no need for any special diagnostic procedures except for a chest x-ray, urinalysis, and an IVP in the appropriate cases.

Relationship of Estrogen and Progesterone Receptors to Prognosis in Breast Cancer

GARY A. GELBFISH, M.D., ANTHONY L. DAVIDSON, M.D., SAMUEL KOPEL, M.D., BARBARA SCHREIBMAN, M.D.,
JOSEPH S. GELBFISH, M.D., GEORGE A. DEGENSHEIN, M.D.,† BURTON L. HERZ, M.D.,
and JOSEPH N. CUNNINGHAM, M.D.

From the Department of Surgery, Maimonides Medical Center, Brooklyn, New York

To ascertain the role of estrogen (ER) and progesterone (PR) receptors as prognostic indicators of resectable breast cancer, the records of 204 patients were analyzed whose receptor studies were done at the Maimonides Medical Center from 1975 to 1983. All patients had radical or modified radical mastectomies and did not show any evidence of distant metastases at the time of operation. Median follow-up was 37 months. An additional 117 patients received some form of adjuvant therapy, mainly chemotherapy, and were analyzed separately. Life table analysis using the log rank test for measuring significance, and a Cox multivariate analysis was performed. At 48 months, 22% of the ER positive (ER+) group *versus* 33% of the ER negative (ER−) group had recurred as compared to 16% and 35% for the PR+ *versus* PR− groups, respectively. Life table analysis of the disease free interval (DFI) showed that the difference between the ER+ and ER− groups was not significant ($p > 0.1$), while the difference in DFI between the PR+ and PR− groups was significant ($p < 0.05$). Multivariate analysis revealed that the most important factors in predicting the DFI were nodal status ($p < 0.001$), tumor size ($p < 0.025$), and progesterone receptor status ($p < 0.05$). Estrogen receptor status was not found to be significant. In conclusion, PR− patients have a shorter DFI than PR+ patients and that PR status is a more valuable predictor of DFI than ER status.

THE IMPORTANCE of hormonal receptors in predicting the likelihood of response to hormonal manipulation in patients with metastatic breast cancer is well established.[1] Patients who are hormone receptor-positive are likely to respond to a variety of hormonal treatments whereas receptor-negative patients virtually never respond. This probably accounts for the longer survival of receptor-positive patients.

Less clear, however, is the possible influence of hormonal receptors on the likelihood of remaining disease free. Most early studies on this subject focused on the estrogen receptor content. Progesterone receptor measurement did not enter routine clinical practice until the late 1970s, and the relationship between the PR and prognosis is less well studied. Since Horowitz and McGuire first proposed the value of the progesterone receptor as a clinical tool, attention has been focused at defining its utility as a predictor of prognosis.[2]

There is a controversy in the literature regarding the value of estrogen receptors in predicting the disease free interval (DFI).[3-9] This variance in the literature may be due to several factors including differences in laboratory methodology and standardization, variations in study entry criteria regarding stage and primary treatment modalities, and statistically insignificant study samples or follow-up periods.

Another significant methodologic difference is the inclusion in many published series of patients who have received hormonal and/or cytotoxic adjuvant therapy. Adjuvant therapies have been shown to prolong the DFI in various subsets of patients.[10-13] Thus, the inclusion of a significant fraction of patients who received adjuvant therapy in all probability bias any evaluation of the predictive value of hormonal receptors on the natural history of surgically treated breast cancer.

The present report analyzes a series of 204 patients who were not treated with any adjuvant therapy, eliminating this confounding variable. We analyzed the effects of estrogen and progesterone receptors on the DFI and sought to identify other factors that might have an impact on the prognosis of breast cancer.

Stage II	100 (49%)
Stage III	35 (17%)

Methods

Estrogen receptor determinations have been performed in our laboratory since 1974 and progesterone receptors since 1975. Between 1975 and 1977 the sucrose density gradient method was used, and later replaced by dextran-coated charcoal. The assay was considered negative if <3 fmol of receptor protein/mg of cytosol protein was present; borderline was determined at 3–10 fmol and positive for >10 fmol. For the purpose of this study all borderline values were considered positive. The technique of receptor analysis is described elsewhere.[14]

All patients in this study had localized breast cancer and underwent either a radical or modified radical mastectomy. Receptor studies were done on the primary tumor. Any patient who had evidence of metastatic disease at the time of surgery or previous breast malignancy was excluded. A total of 321 patients satisfied the above criteria and were available for analysis. Of these, 117 received some form of adjuvant therapy and were analyzed separately. A total of 204 patients remained, and they constitute the basis of this report.

For the purposes of this study adjuvant therapy is defined as any postoperative treatment: hormonal, cytotoxic, and/or radiation therapy. No attempt was made to differentiate among these groups since the subgroups were too small for any meaningful analysis.

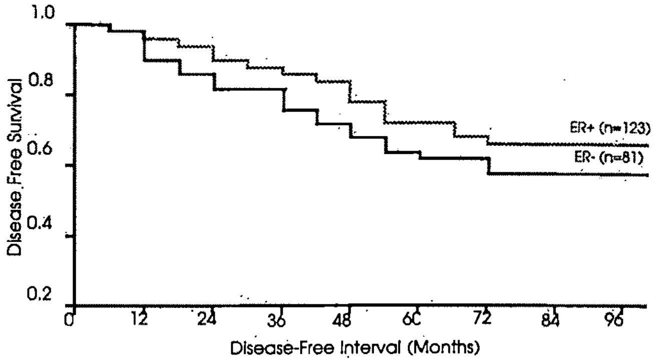

FIG. 1. Life table analysis of ER+ *versus* ER− ($p > 0.1$). Only patients not receiving adjuvant therapy are included.

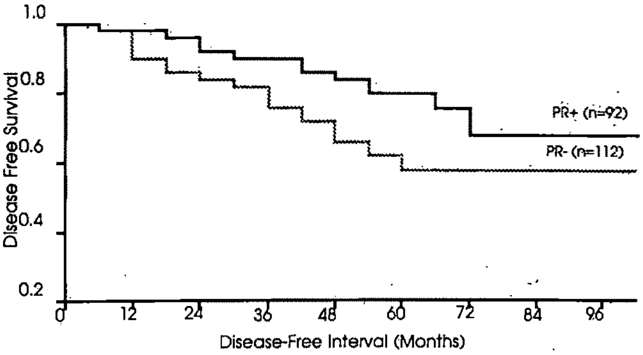

FIG. 2. Life table analysis of PR+ *versus* PR− ($p < 0.05$). Only patients not receiving adjuvant therapy are included.

The date of recurrence was the date of clinical detection of recurring tumor. Follow-up data was obtained from hospital and clinic records and from attending physicians.

Life table analyses were performed using standard actuarial methods. Differences between curves were analyzed using the log rank test for censored survival data. Cox's partially nonparametric regression model was used to evaluate the contribution of various factors in the prediction of the DFI.[15] Computations were performed with SAS computer programs release 82.3.

Results

Table 1 presents patient characteristics. It should be noted that a high percentage of our patients are postmenopausal, a patient group more likely to have a positive hormonal assay.

After 48 months, 8% of stage I patients had recurred *versus* 22% and 60% for stages II and III, respectively. This increased to 21%, 33%, and 70%, respectively, for those patients with 72 month follow-up. In all instances, these differences were significant ($p < 0.01$). The recurrence rate at 48 months for the ER+ *versus* ER− group was 22% *versus* 33%, respectively, while for the PR+ *versus* PR− group it was 16% *versus* 35%, respectively.

Figure 1 compares the ER+ *versus* ER− groups. The ER+ group showed a longer DFI, but this trend was not statistically significant ($p > 0.1$). Figure 2 shows the life table comparison of PR+ *versus* PR− patients. This difference was significant ($p < 0.05$).

Table 2 reports the results of hormonal receptor determinations.

The group of 117 patients who received some form of adjuvant therapy were included in the study group and

TABLE 2. *Receptor Values*

ER+	123 (60%)
ER−	81 (40%)
PR+	92 (45%)
PR−	112 (55%)
ER+/PR+	82 (40%)
ER+/PR−	41 (20%)
ER−/PR+	10 (5%)
ER−/PR−	71 (35%)

the life table analysis was repeated. Again, the difference between the ER+ and ER− groups was not found to be significant ($p > 0.1$), while the difference between the PR+ and PR− groups was significant ($p < 0.025$). The life tables for estrogen and progesterone are shown in Figures 3 and 4, respectively.

A Cox multivariate analysis was performed to measure the significance of each of the following factors: nodes (0 vs. 1-3. vs. >3) $p < 0.001$, tumor size (T_1 vs. T_2 vs. T_3), $p < 0.025$, progesterone receptor (+ vs. −) $p < 0.05$, estrogen receptor (+ vs. −) $p > 0.25$, age, $p > 0.5$, and adjuvant therapy (yes vs. no) $p > 0.25$. These factors are listed in Table 3. These results show that PR positivity, independent of all other factors, is a significant determinant of the DFI. This is not so for the estrogen receptor.

Discussion

The finding of an insignificant difference between the estrogen positive and negative groups is not unexpected and has been reported previously. Kinne et al.[4] found only borderline ($p = 0.06$) significance after 14 months of follow-up despite a very large series containing 1034 patients. Hilf et al.[5] and Skinner et al.[7] also did not find a significant difference. The majority of studies, however, do show a difference.[6,8,9] Wide variation in patient population size, length of follow-up, and the inclusion of patients who received adjuvant therapies are among factors likely to be responsible for the divergent results.

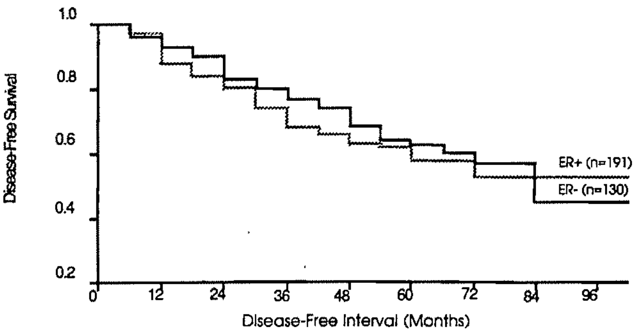

FIG. 3. Life table analysis of ER+ *versus* ER− ($p > 0.1$). Patients receiving adjuvant therapy are included.

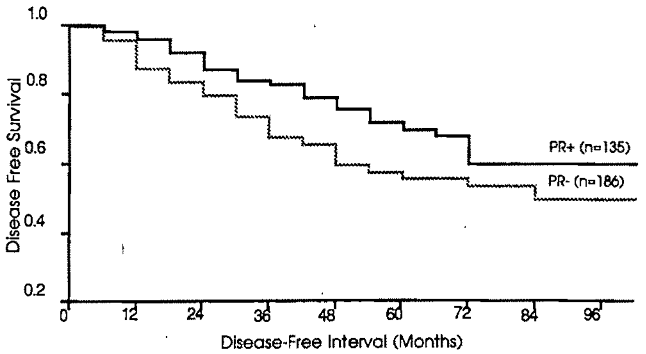

FIG. 4. Life table analysis of PR+ *versus* PR− ($p < 0.025$). Patients receiving adjuvant therapy are included.

The potential value of the progesterone receptor content has not been studied as extensively as the estrogen receptor. Published data suggest that it is at least equal to if not better than the estrogen receptor for predicting the DFI.[8,16] In this study the progesterone assay was a more sensitive indicator of recurrence potential of the tumor. In addition, the results of the Cox regression analysis indicated that unlike progesterone, estrogen was not a significant independent predictor of the DFI when all the other factors are controlled.

In a recent study, Clark et al.[8] analyzed 189 patients with stage II disease using similar statistical methods. Their patient group differed from those in the present study in that all patients had received adjuvant chemotherapy and two out of three had received tamoxifen. Median follow-up was 32 months. Significant differences in the DFI were found using life table analysis of the data subdivided according to either estrogen or progesterone receptor content. Despite these life table findings, analysis using the Cox multiregression model showed that estrogen receptor was not a significant independent variable. Thus, the study by Clark et al.[8] and ours both show that once the other factors in the regression analysis are known, namely, nodal status, tumor size, and progesterone receptor content, the knowledge of the estrogen receptor content is of little additional help in predicting the DFI. Our data also extend these observations to a group of patients treated solely by primary surgery without adjuvant therapies.

TABLE 3. *Factors Considered in the Multivariate Model*

Factor	p Value
Nodes (0 *vs.* 1-3 *vs.* >3)	<0.001
Tumor size (T_1 *vs.* T_2 *vs.* T_3)	<0.025
Progesterone receptor (+ *vs.* −)	<0.05
Estrogen receptor (+ *vs.* −)	>0.25
Age	>0.5
Adjuvant therapy (yes *vs.* no)	>0.25

Treatment with tamoxifen, with or without cytotoxic chemotherapy, has been shown to prolong the DFI of postmenopausal patients who are ER+.[10,13] Cytotoxic chemotherapy has been convincingly demonstrated to prolong the DFI of premenopausal patients without apparent regard to hormonal status.[11,12] Whether chemotherapy exerts a significant effect in postmenopausal patients is still debated.[17] Thus, the effect of adjuvant therapy on the DFI can be difficult to predict and will likely exert dissimilar effects on various subsets. For example, Lippman et al.[18] reported that ER+ tumors respond less well to adjuvant therapy than ER− tumors. Kiang et al.[19] and others,[20,21] however, have come to the opposite conclusion. Others have not found any relationship or have found a relationship only in premenopausal women.[5,22,23] Regardless of the effect on specific subsets, adjuvant therapy is likely to confound the evaluation of the relationship of receptor status on the natural prognosis of breast cancer.

With the widespread implementation of adjuvant treatments, especially chemotherapy, commencing in the late 1970s, adequate study of the natural history of breast cancer relative to hormonal receptors became increasingly difficult. In contrast to other reported series, the current group of patients consists entirely of patients who never received postmastectomy treatment. Our laboratory began to analyze hormonal receptors in 1974, thus affording us an opportunity to evaluate the potential prognostic significance of estrogen and progesterone receptors in a cohort of patients treated with mastectomy alone. The homogeneity of the group with regard to treatment removes adjuvant therapy as an additional confounding variable, a problem that hampers evaluation of a number of published series.

Knowledge of the relationship of hormonal receptor status and the natural history of the disease is of some importance in patient management after primary surgery. Conventionally, adjuvant chemotherapy is withheld from stage I patients. It has been suggested that there is a subgroup of patients at high risk for early recurrence who may well be candidates for treatment. Among the proposed high risk criteria is receptor negativity.[24,25] Our study supports this view, especially with regard to the progesterone receptor.

In the present study the inclusion of our adjuvant therapy group in the life table analysis did not alter the results (Figs. 3 and 4). The difference in the DFIs remained significant in the PR+ *versus* the PR− groups. However, patients treated with adjuvant therapy did worse than those not so treated. Presumably, this is a patient selection artifact since patients with more advanced disease were more likely to be treated with adjuvant therapy. Fifty per cent of stage III patients had adjuvant therapy whereas only 12% of those with stage I were so treated. In addition, those patients entering the study at a later date were more likely to have adjuvant therapy. This is also supported by the lack of significance of adjuvant therapy in the regression model. In essence, the decreased DFI observed in the adjuvant group can be attributed to changes in the other significant factors of the model, namely, nodal status, tumor size, and progesterone. It must be cautioned that this study was not designed to analyze adjuvant therapy, and no conclusions can be drawn from these data about its efficacy.

Thus, this study confirms that the progesterone receptor is a valuable indicator of the recurrence potential in breast cancer, independent of estrogen receptor positivity and treatment with adjuvant therapies.

Host and Tumor Responses to Varying Rates of Nitrogen Infusion in the Tumor-bearing Rat

MARTIN B. POPP, M.D., STEPHEN C. WAGNER, EVELYN B. ENRIONE, PH.D., and OMAR J. BRITO, M.D.

From the Department of Surgery, Cincinnati Veterans Administration Medical Center, Cincinnati, Ohio

The influence of variations in nitrogen content of nutritional substrate available to the tumor-bearing (TB) host on tumor growth and host have not yet been completely defined. One hundred fifty-two growing Fischer 344 rats were either transplanted with a sarcoma (TB) or injected with saline (NTB, day 0), had aseptic placement of superior vena cava catheter (day 14), and were infused with total parenteal nutrition solutions (days 18–28). Isocaloric solutions (approximately 50 kcal/d) contained either 0%, 5%, 16%, 33%, 67%, 100%, 133%, or 167% of normal intake of an adequate amino acid mixture. Final tumor weight in the 5% group (23.4 ± 3.0 g) was significantly less than tumor weights of all other groups (range: 33.3 ± 3.3 to 42.6 ± 11.3) ($p < 0.05$). The carcasses of TB animals were slightly smaller than NTB animals but showed no major alterations in protein, fat, or water composition. This study suggests that the tumor can be starved selectively by strictly nutritional means with complex accompanying host carcass and organ changes.

OPTIMUM NUTRITIONAL SUPPORT for the tumor-bearing (TB) host remains undefined. Numerous controlled clinical trials of standard intravenous (I.V.) hyperalimentation with a variety of tumor types and under a variety of treatment conditions have revealed little evidence of patient benefit.[1,2] The sole exception is a trial of I.V. hyperalimentation given before operation to patients with upper gastrointestinal malignancies, which demonstrated decreased postoperative morbidity and mortality rates.[3]

Experimental work in inbred rats with transplantable tumor systems has also failed to reveal significant host benefit with aggressive nutritional support.[4-15] Further, tumor growth stimulation out of proportion to host carcass support has been demonstrated in most tumor-rat systems in which it has been carefully examined.[4-10] One clinical study in head and neck cancer patients[16] and one study of colorectal cancer patients also suggest similar tumor stimulation in man.[17] The vast majority of controlled clinical data can be interpreted as showing that little benefit to the host and possible detriment from tumor stimulation result from aggressive nutritional support.

These data all suggest that nutritional approaches other than standard balanced nutritional solutions should be explored in an attempt to find a nutritional therapy that would benefit the host while being detrimental to the tumor. Several studies with conflicting results have been undertaken in which fat was exchanged for carbohydrate as the basic energy source.[8,11] In our study the response of a rat-tumor system to isocaloric variation in total nitrogen infusion over a range of 0–167% of normal has been systematically evaluated. The results suggest that low levels of nitrogen infusion selectively starve the tumor.

Methods

Experimental Design

Male Fischer 344 rats of approximately 150 g were acclimated to the laboratory and a synthetic casein-based diet[18] for three days. TB rats were randomly selected to undergo tumor transplantation with 1×10^6 methylcholanthrene-induced tumor cells. The origin of this tumor, methods for preparing and checking the viability of single cell suspensions, and the natural history of tumor growth in rats of this size have been described in detail.[19] Rats selected as nontumor-bearing (NTB) control animals were anesthetized with pentobarbital (30 mg/kg) in the same manner as TB animals but were injected with 0.5 mL of a sterile saline solution. Following either tumor inoculation or saline injection on day

Submitted for publication: April 2, 1987.

0, rats were allowed to resume the casein diet on an *ad libitum* basis for 14 days.

On the 14th day the rats were again anesthetized with pentobarbital (30 mg/kg) and had aseptic placement of superior vena cava catheters, which were sterilely connected through flexible spring catheter shields to the tops of metabolic cages.[20] The system was kept patent with a daily injection of 1.0 mL of heparinized saline (10 U/mL) for the next 4 days. The 4-day period was selected to allow rats to recover completely from the stress response to the operation.[20,21]

Nutritional Support

On day 18 of the experiment, rats were randomly allocated to groups to begin a 10-day period of nutritional support with total parenteral nutrition (TPN) solutions of varying nitrogen content. The nutritional solutions had mineral, fat, and vitamin contents that have been documented to support normal growth of these rats over a 21-day period.[18] The nitrogen content consisted of a balanced amino acid mixture with the same ratio as that derived from hydrolized casein.[22] The quantity of amino acids in the solutions was 0%, 5%, 16%, 33%, 66%, 100%, 133% and 167% of normal nitrogen intake.[18] The glucose content of each solution was adjusted to make all of the experimental solutions isocaloric. The amino acid mixture was assumed to have 4.00 kcal/g, and the anhydrous glucose (Sigma Chemical Co., St. Louis, MO) was assumed to have 3.74 kcal g. Additional control groups of rats consisted of one group (CON) of both TB and NTB rats, which were killed on day 18 of the experiment, and groups of TB and NTB orally fed control rats, which were allowed to eat *ad libitum* a solid amino acid-based diet (AAD),[18] which was nearly identical to the diet infused nutritionally in the 100% group of TPN rats.

Evaluation of Results

On days 18, 21, 23, 25, and 28 of the experiment, rat weights and tumor dimensions were determined. The total weights of nutritional solutions infused and solid diet ingested were also measured over this 10-day period. On day 28, rats were killed by injection of an overdose of pentobarbital anesthesia. TB rats had the tumors excised and weighed. Blood was collected for determination of hematocrit, white blood cell count, and differential count. The gastrointestinal tracts were opened and all undigested food and stool was collected and weighed. Carcass weights were determined by subtracting tumor weight and gastrointestinal tract content weight from total body weight for TB rats and gastrointestinal tract content weight from total body weight for NTB rats. Complete postmortem examinations were performed. No evidence of metastatic tumor was detected in any animal. The heart, lungs, stomach, small intestine, colon, liver, spleen, and testes were all dissected free, cleansed of fat, and weighed.

All of the viscera were then frozen with the entire rat carcass including the skin for later carcass composition analysis for total water, fat, and protein content. Tumors were similarly frozen for composition analysis. The details of these analytic procedures have been described previously.[4,5,18] Briefly, the carcasses were cut into small pieces and autoclaved at 220 C for 15 minutes to soften the pelts. They were homogenized in 1 L of water using a high-speed homogenizer. Aliquots (approximately 200 g) of the homogenate were then freeze-dried for 1 week until a stable weight was reached. The final weight of dry material in the aliquot allows calculation of the total quantity of dry material in the original carcass. Subtraction of this from the total carcass weight yields the total body water content. The dry material was then analyzed for total nitrogen content using 0.5 g samples and a macro-Kjeldahl technique. It was also analyzed for total fat content with a petroleum-ether extraction. The weight of total dry material in the rat and the fat content per gram and nitrogen content per gram allows calculation of total fat and nitrogen in the original carcass. Multiplication of total nitrogen by 6.25 yields a total protein content. Tumor composition is determined in a similar manner. These independent analyses routinely account for 94–96% of rat carcass and 98% of tumor weight.[4,5,18,24] These results are consistent with body composition data, which indicate that approximately 5% of total carcass is skeleton that is not in water, protein, or fat compartments.

Distributions of Rats into Groups and Calculations

Initially, rats were randomly assigned to nutritional groups ranging from 33% to 167% of normal nitrogen intake and the CON and AAD groups. Six rats were placed in each TB group and five in each NTB group. Preliminary analysis of the results suggested little influence on tumor growth from variations of nitrogen intake over these ranges. Additional groups of animals were then tested at the 16%, 5%, and 0% levels. These results suggested that tumor growth might be inhibited at the lower ranges. Because these latter results were obtained with groups that were not a part of the original randomization, it was decided that additional animals should be tested at these lower ranges with concomitant randomization of TB animals to the 66% and 100% groups. Additional animals were also initially placed in TB-133 and TB-167 groups because rats in these groups tended not to survive the final 10 days of the experiment. The final number of animals starting in each ex-

perimental group is indicated in Table 1. Since the basic trends observed in the first analysis of the 0%, 5%, and 16% group were observed in the second experiment with these groups, all of these data have been combined and analyzed as a single experiment.

Mean values and SEM were calculated for all of the variables studied. Mean values were initially compared with an analysis of variance.[23] Correlation coefficients and regression analysis were used to analyze data from TPN groups in which nitrogen intake was varied.[23]

Results

Rat Survival and Nutrient Intake

A total of 152 rats began the experimental protocol. Twenty-two rats (12 TB and 10 NTB) failed to complete the 28-day experiment for mechanical or infectious reasons (catheter infiltration, catheter disconnection, or catheter infection as determined by postmortem examination).[20] Five attempts to support TB rats through the 10 days of nutritional supplementation with 0% nitrogen all resulted in animal deaths between the 23rd and 25th experiment days. Only two of seven TB-133 rats and three of eight TB-166 rats survived until day 28. None of these deaths could be related to mechanical or infectious problems, and all occurred between days 25 and 28 of the experiment. All data from the 22 animals having mechanical or infectious failure and the five 0% animals have been excluded from further consideration. Tumor weight calculations from the 15 TB-133 and TB-167 rats who survived until day 25 have been included. The final numbers of rats completing the study and their nutrient intakes are illustrated in Table 1.

There were no significant differences in the caloric intakes of the infused rats. The differences in nitrogen intake were significantly different ($p < 0.001$). Both the caloric and nitrogen intake of the TB-AAD rats were significantly less than the NTB-AAD rats ($p < 0.001$).

Blood and Organ Weight Changes

All TB rats except the control rats were anemic with hematocrits ranging from 23.6 ± 2.6% to 32.7 ± 3.4%. These hematocrits were significantly different ($p < 0.05$) than the TB-CON rats and all of the NTB rats where hematocrits ranged from 39.0 ± 0.6% to 48.7 ± 2.7%. White blood cell counts were elevated in all TB groups except for TB-CON and ranged from 12.7 ± 1.1 to 22.8 ± 2.4 $(\times 10^3/\text{mm}^3)$. The TB-CON and all of the NTB group means ranged from 5.9 ± 1.6 to 10.5 ± 0.8 $(\times 10^3/\text{mm}^3)$. These increased white blood cell counts could be attributed to polymorphonucleocytes, which ranged from 56.7 ± 11.4% to 71.0 ± 2% in the TB groups and 20.0 ± 3.2% to 52.0 ± 3.3% in the TB-CON and NTB series.

A complex group of interrelationships between organ weight, changes in nitrogen infusion, oral *versus* I.V. nutritional support, and TB or NTB status was observed. Liver, heart, and kidney weights all increased linearly with rate of nitrogen infusion (Fig. 1). TB groups had mean organ weights greater than NTB groups at each level of infusion for these three organs. TB rats receiving the AAD had significantly smaller livers than NTB rats ($p < 0.05$). There were no differences in heart or kidney weights between TB and NTB rats receiving the AAD. The stomach, small bowel, and colon weights demonstrated a nonlinear tendency to be lowest at the 5% and 16% rates of nitrogen infusion (Fig. 2). NTB animals had elevated stomach weights when compared to TB animals at all levels of infusion. No difference in TB and NTB rats was demonstrated in small bowel or colon weights. Free-feeding TB and NTB rats eating the AAD had markedly higher stomach and small bowel weights when compared to rats receiving nutrients by TPN infusion. Free-feeding NTB rats had greater stomach and small bowel weights than TB rats. Spleen weights were lowest in the low nitrogen infusion

TB and NTB groups (Fig. 3). They increased in a nonlinear fashion with increasing levels of nitrogen infusion, with TB rats developing much larger spleens than NTB rats at high rates of nitrogen infusion. Lung weights were lowest in the 5% and 16% infused groups. No other discernible patterns were evident in lung or testes weights (Fig. 3).

Carcass Weight and Composition Changes

There were no significant differences in mean total body weights among all groups of animals on either day 0, day 14, or day 18. Day 28 total body weights varied directly with the rate of nitrogen infusion for TB rats (r = 0.55, p < 0.001) and for NTB rats (r = 0.70, p < 0.001, Fig. 4). Total body weights of TB rats were greater than for NTB rats (Fig. 4). Examination of carcass weights (carcass weight = total body weight − tumor weight − gastrointestinal content) revealed similar patterns of weight with regard to rate of nitrogen infusion (TB: r = 0.40, p = 0.003; NTB: r = 0.69, p < 0.001). Carcass weights of TB animals tended to be lower than NTB animals (Fig. 4). The day 28 total body weights of TB-AAD rats were similar to the day 28 total

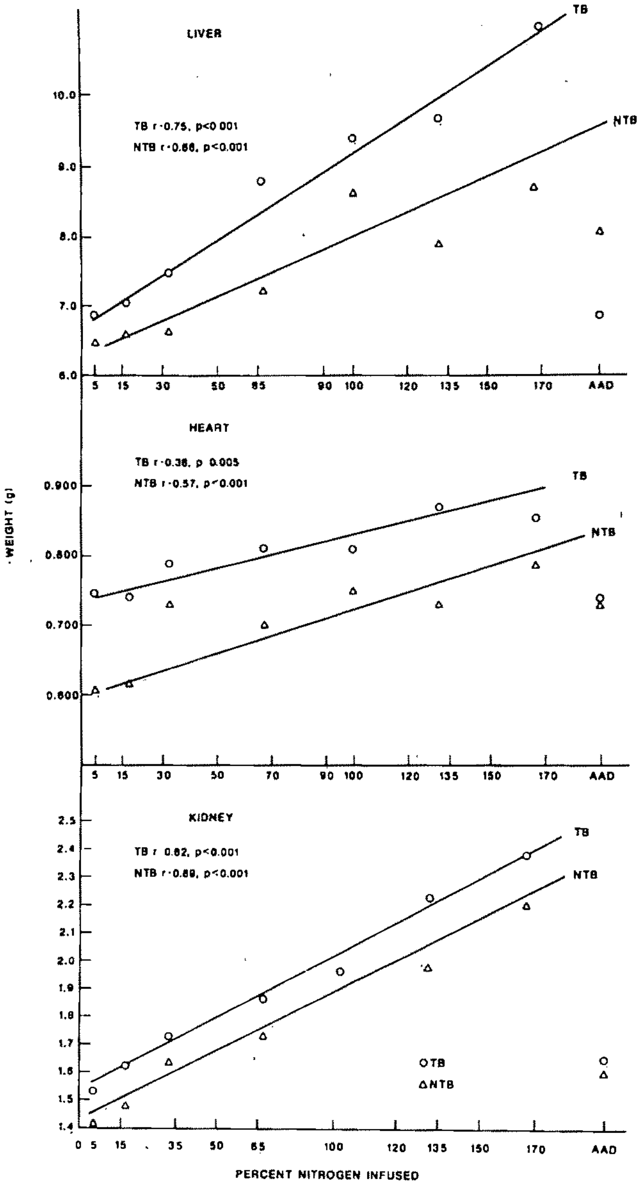

FIG. 1. Response of liver, heart, and kidney to TB and NTB status, to changes of nitrogen substrate infusion from 5–167% of normal, and to oral diet (AAD). Data points are mean values, and correlation coefficients are calculated with infusion data only.

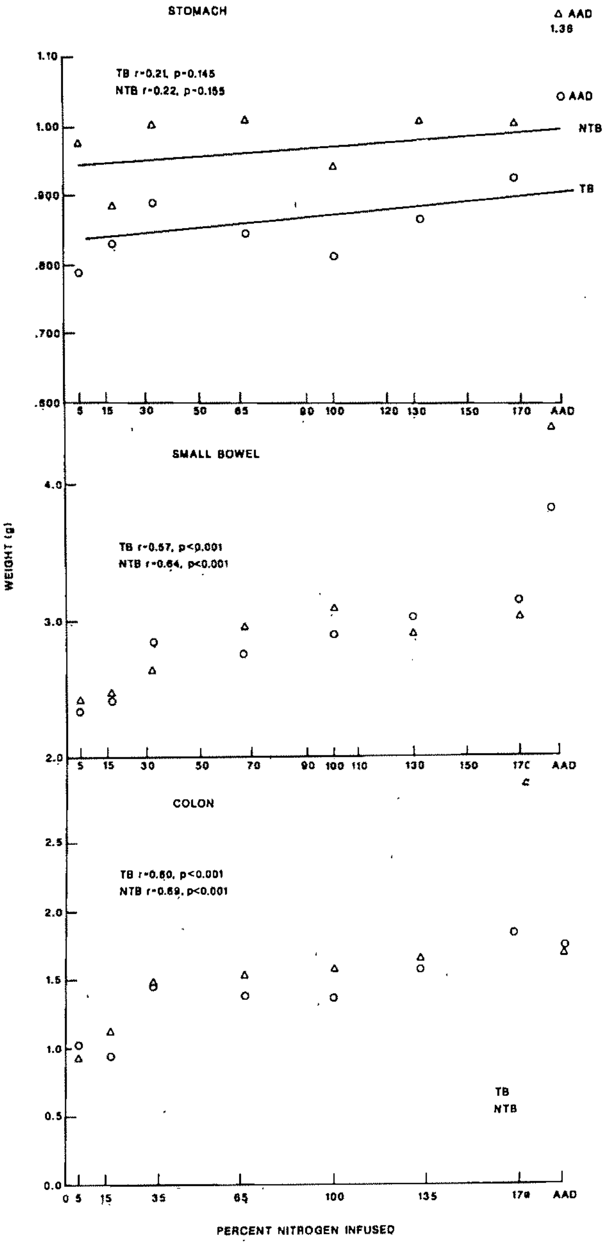

FIG. 2. Response of stomach, small bowel, and colon to TB and NTB status, to changes of nitrogen substrate infusion from 5–167% of normal, and to oral diet (AAD). Data points are mean values, and correlation coefficients are calculated with infusion data only.

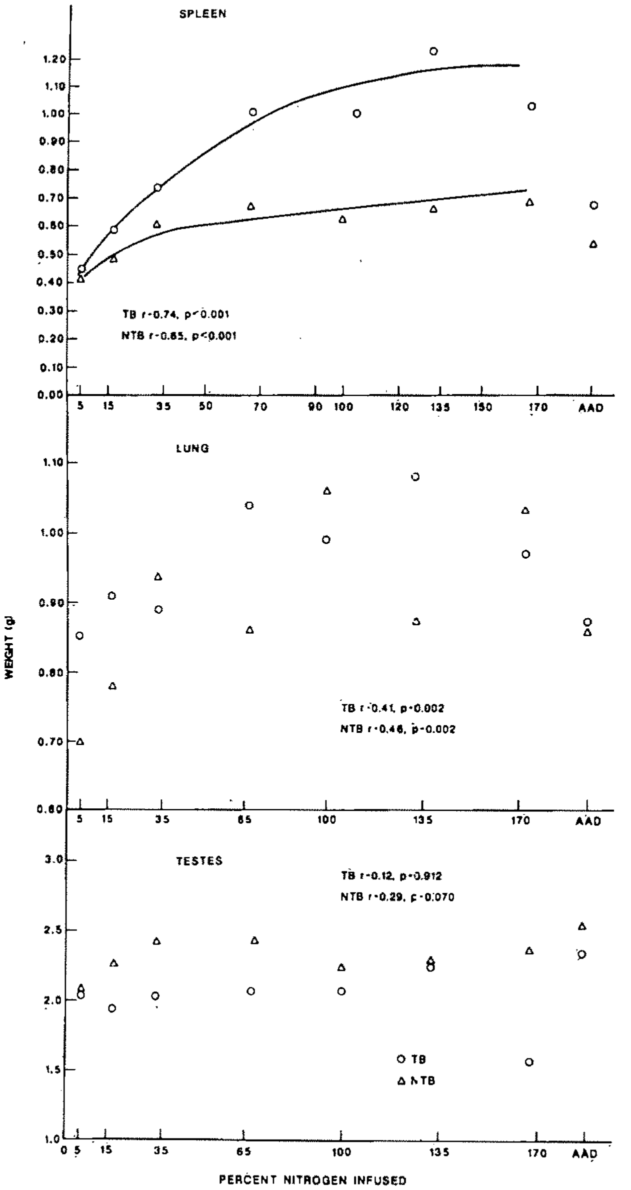

FIG. 3. Response of spleen, lung, and testes to TB and NTB status, to changes of nitrogen substrate infusion from 5–167% of normal, and to oral diet (AAD). Data points are mean values, and correlation coefficients are calculated with infusion data only.

body weights of NTB-AAD rats. The final carcass weights of TB-AAD rats were significantly less than the final carcass weights of NTB-AAD rats (p < 0.001).

Total carcass content of water tended to be lowest in the 5%, 16%, and 33% infusion groups of rats in both the TB (r = 0.30, p = 0.034) and NTB (r = 0.48, p = 0.001) groups (Fig. 5). Carcass protein content correlated significantly with infused nitrogen intake for NTB rats (r = 0.62, p < 0.001), but not for TB rats (r = 0.19, p = 0.179, Fig. 6). No significant differences were detected in the fat content (Fig. 7) or in percentage of water, TB protein, or fat content between any of the infused groups (Figs. 5–7). All of the infused groups had a higher total body fat content when compared to orally fed control animals (Fig. 7).

Tumor Growth and Composition

Tumor weight varied significantly with rate of nitrogen infusion (r = 0.35, p = 0.012). TB-005 animals had

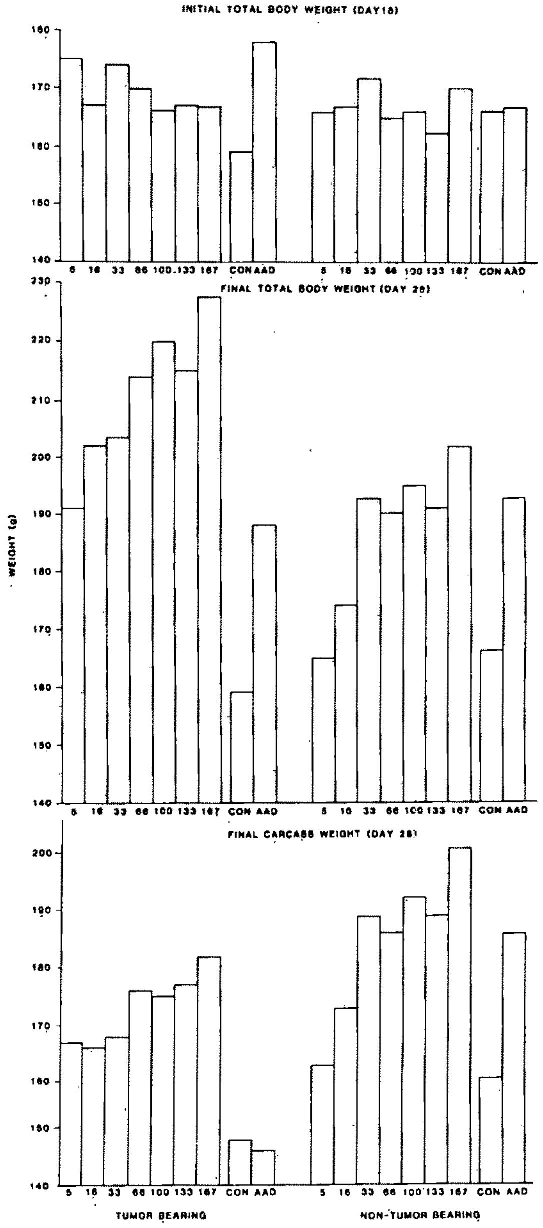

FIG. 4. Mean values of initial total body weight, final total body weight, and final carcass weight (carcass weight = total body weight − tumor weight − gastrointestinal tract content) for TB and NTB rats infused with TPN solution with nitrogen content varying from 5–167% of normal. Mean weights of a cohort of control rats killed on the initial day (day 18) of infusion (CON) and groups maintained on an oral diet (AAD) are also indicated. No significant differences were detected among mean initial total body weights. Final mean total body weights (TB: r = 0.55, p < 0.001; NTB: r = 0.70, p < 0.001) and carcass weights (TB: r = 0.40, p = 0.003; NTB: r = 0.69, p < 0.001) varied directly with rate of infused nitrogen.

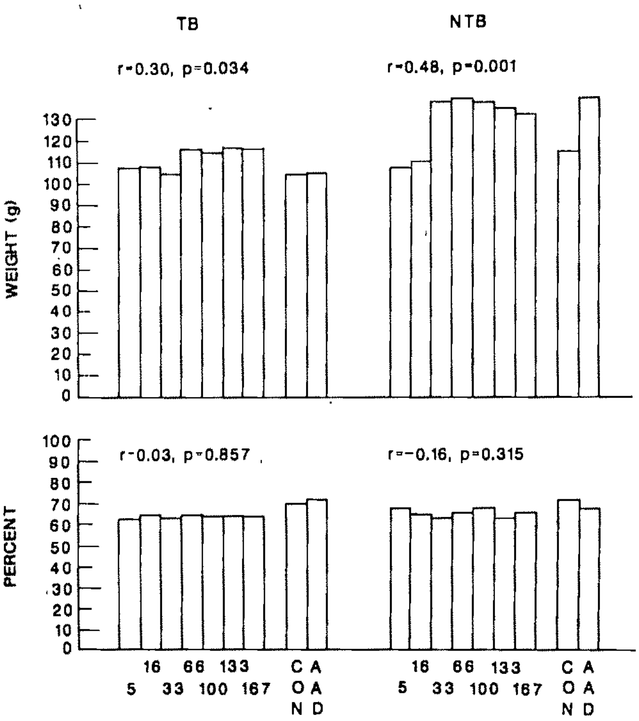

FIG. 5. Carcass water content expressed as absolute weight and as a percentage of carcass weight for rats receiving TPN infusions, control rats (CON), and orally fed rats (AAD). Each bar is a group mean value, and correlation coefficients are calculated with infusion data only.

the lowest tumor growth rates, whereas TB-167 had the highest (Fig. 8). Differences were less prominent at infusion rates between these extremes (Fig. 8, Table 2). The ratio of tumor weight to carcass weight (0.140) was lowest in the TB-005 animals and similar in the remainder of the infused TB rats (ratio range: 0.198 to 0.234, Table 2). The ratio was highest (0.272) in the TB-AAD group.

Tumor protein content was significantly related to the rate of nitrogen infusion ($r = 0.48$, $p < 0.001$, Table 2). No significant relationships were detected between tumor water or fat content and rate of nitrogen infusion (Table 2).

Discussion

These data indicate the effects on a host-tumor system of widely varying nitrogen intake associated with constant caloric, fat, mineral, and vitamin intakes. The survival data indicate that both the extremes, of either no nitrogen (0%) or high nitrogen (133% or 167%), are poorly tolerated by the TB host. No TB animals survived the 10-day experiment at 0%, and survival was difficult to obtain in the TB-133% and TB-167% groups (Table 1). When mechanical and infectious failures were eliminated, survival was easy to obtain in all of the other TB groups (5–100%) and in all of the NTB groups (5–167%).

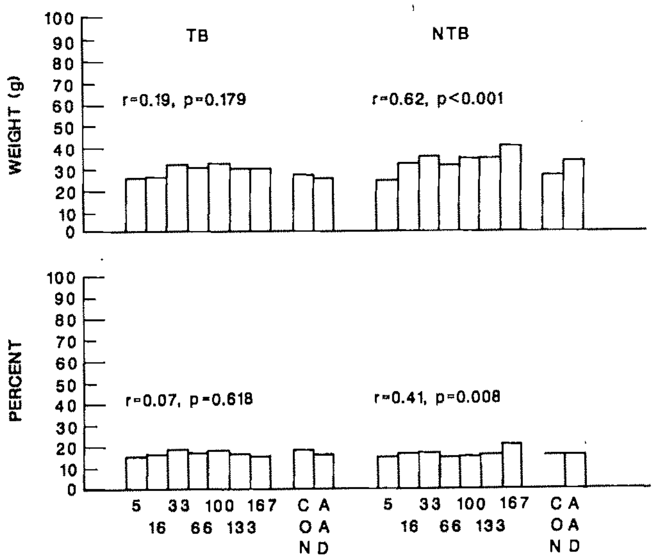

FIG. 6. Carcass protein content expressed as absolute weight and as a percentage of carcass weight for rats receiving TPN infusions, control rats (CON), and orally fed rats (AAD). Each bar is a group mean value, and correlation coefficients are calculated with infusion data only.

The blood studies, organ weight data, and carcass analysis data can be examined to determine possible pathophysiology and causes of death in the TB animals at both extremes of nitrogen intake. The anemia and polymorphonucleocyte response have been repeatedly observed in this model.[4,5] There were no correlations of hematocrit or white blood cell count with the rate of nitrogen infusion in this experiment, and there have been no correlations of tumor size with these parameters

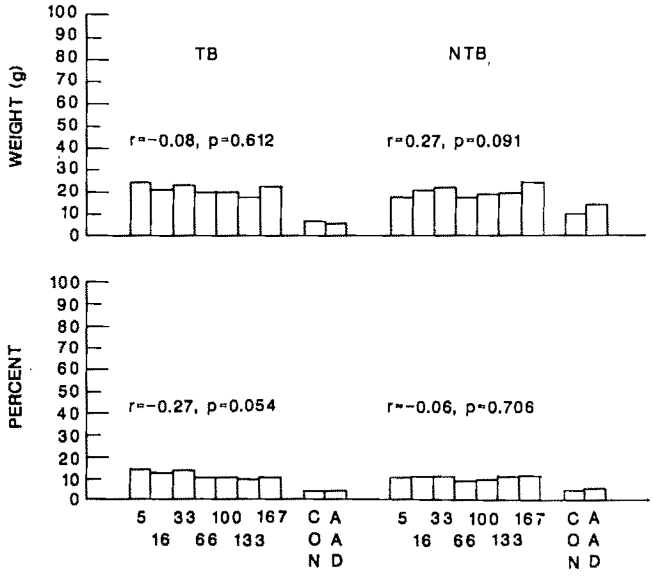

FIG. 7. Carcass fat content expressed as absolute weight and as a percentage of carcass weight for rats receiving TPN infusions, control rats (CON), and orally fed rats (AAD). Each bar is a group mean value, and correlation coefficients are calculated with infusion data only.

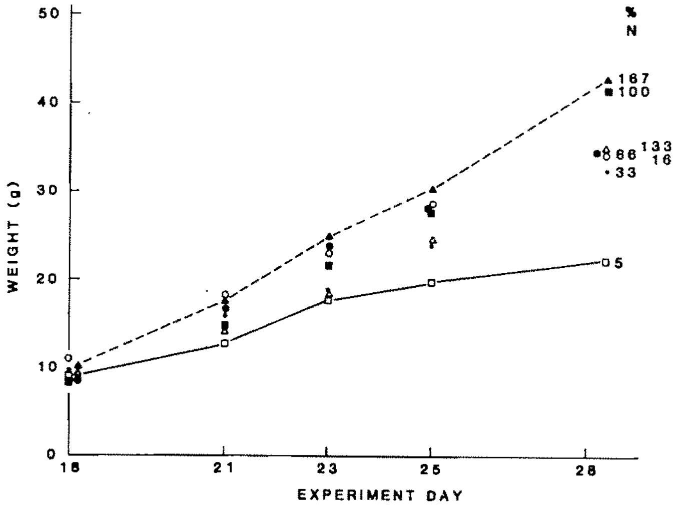

FIG. 8. Mean tumor weights calculated from *in vivo* measurements[6] (days 18 to 25) and final measured (day 28) mean tumor weights for rats receiving isocaloric TPN infusions with nitrogen content ranging from 5–167% of normal. Tumor growth lines are graphed only for the most rapidly growing T = 167% group and most slowly growing T = 5% group.

in either this experiment or other experiments.[4,5] The mechanism for the anemia is totally unknown. The elevated white blood cell and count shift in differential count can be hypothesized to be a reaction to areas of tumor necrosis. These data suggest that both the anemia and leukocytosis are nonspecific stresses in the TB host when significant tumor volume is reached. They are not present in the NTB host, and they probably are causes of increased mortality rates and poor tolerance of nutritional stresses in the TB host.

These organ weight data suggest several different patterns of pathophysiology. The liver, heart, and kidney weights all suggest a nonspecific detrimental effect of the tumor acting at all levels of nitrogen infusion and a clear relationship of weight to the rate of nitrogen infusion (Fig. 1). This nonspecific effect of the tumor, which causes increased liver, heart, and kidney weights, might be explained by the anemia and toxic factors causing the granulocyte response. The extra demands of anemia and toxicity require both increased cardiac output and increased glomerular filtration leading to hypertrophy of these organs. The liver also usually responds to nonspecific toxic stress with fat accumulation and increased weight. This phenomenon has been repeatedly observed in this model.[4,5] Alternative hypotheses such as tumor-produced growth factors causing organ hypertrophy cannot be excluded. The linear response of liver, heart, and kidney to the rate of nitrogenous substrate infusion would also be expected. Increased liver capacity would be required to process the increased amino acid load, and both increased kidney perfusion (cardiac output) and increased renal clearance of nitrogen as ammonia and urea would be required by the host to cope with the increasing levels of nitrogen substrate.

The reasons for the observed changes in stomach weights are unclear. Specific responses of stomach weights to the TB state in this model have not previously been observed. Similarly, one would not expect the stomach to be particularly responsive to rate of nitrogenous substrate infusion. The small bowel weights and stomach weights demonstrated a marked decrease in weight when TPN animals are compared to orally fed animals (Fig. 2). This has been repeatedly demonstrated in similar previous comparisons.[18,24] Small bowel, colon, spleen, and lung all demonstrated a tendency toward low weights in the 5% and 16% TB and NTB groups. These changes suggest simple nitrogenous substrate deprivation in rapid turnover tissues that should be substrate-sensitive. The absence of major differences between the TB and NTB groups suggests that the tumor is not particularly successful at competing for nitrogenous substrate with these tissues.

The pattern of spleen weights observed with the changes in nitrogen substrate is of interest. Elevated spleen weights are consistently observed during tumor growth in most of the transplantable rodent-tumor models.[5,7,15] The mechanism of this response is not well understood but probably involves the immunologic re-

TABLE 2. *Tumor Weight and Composition*

sponse to the tumor. Data from this experiment suggest that this mechanism is extremely nitrogen-substrate–responsive since the response almost totally disappears at low levels of nitrogen infusion (Fig. 3).

These total body weight data and carcass weight data (Fig. 4) indicate the influence of the TB state under both infused substrate and free-feeding substrate conditions. Total body weights for all of the infused animals are higher for the TB groups when compared to the NTB groups and are similar in the TB-AAD and NTB-AAD groups. Subtraction of the tumor weights to derive carcass weights (Fig. 4) shows the diminished carcass mass in the infused TB groups and markedly decreased carcass mass in the free-feeding TB-AAD group when compared to the respective NTB groups. These data are consistent with previous studies of this model, which all suggest that decreased carcass mass in the free-feeding animal is largely due to decreased substrate intake[4–6,19] and that the carcass mass in the TB state can be partially preserved with an infusion of adequate nutrients.[4–6] Of particular interest is the relatively similar carcass mass in the TB 5%, 16%, and 33% groups (Fig. 4). These data, along with the body composition data and data regarding the small bowel, colon, spleen, and lung weights all suggest that the tumor is not particularly successful in competing with normal carcass and visceral tissues for limited nitrogenous substrate.

Carcass composition data (Figs. 5–7) simply confirm that the overall carcasses were of similar composition. This is particularly evident when the carcass composition is expressed as a percentage of overall carcass weight. These data indicate that the preservation of carcass mass in the infused TB groups is the result of satisfactory accumulation of lean tissue rather than pathophysiologic accumulation of either fat or water. The tendency of infused groups to accumulate slightly more fat than orally fed groups (Fig. 7) has been observed in other comparisons of infused animals *versus* free-feeding animals[4,18] and remains consistent.

The tumor weight data (Fig. 8) and tumor composition data (Table 2) suggest that the tumor is responsive to the quantity of nitrogenous substrate available and that tumor growth is inhibited at the 5% level of nitrogenous substrate infusion. The finding of decreased tumor growth only at the 5% level with failure of animal survival at the 0% level indicates that a selective beneficial effect to the host-tumor system occurred only in a very narrow range of nitrogen infusions. The low tumor weight to carcass weight ratio (Table 2) and relatively normal carcass composition (Fig. 5–7) indicate a selective detrimental effect of low nitrogenous substrate availability on the tumor.

This finding of tumor inhibition with this balanced amino acid solution is of interest in light of recent determinations by our laboratory and other laboratories of the amino acid substrate requirements of this MCA tumor.[25,26] The work by Miller et al.[25] had demonstrated a major requirement of this tumor for the amino acids glutamine and asparagine. These amino acids have been demonstrated to be important for growth in other tumor systems.[27,29] These latter findings are particularly interesting in that 33% of the amino acid substrate used in the current experiment was composed of glutamine, asparagine, glutamic acid, and aspartic acid.[18] All of these data suggest that further beneficial manipulations in this host-tumor system might result from purely nutritional manipulation of the amino acid composition of the infused formula while keeping the total nitrogen levels in the 5% range.

The results of our study are not unique in demonstrating decreased tumor growth in response to nitrogen deprivation. Early research in the nutrition and cancer field clearly demonstrated that poor nutritional intake and, to a certain extent, protein depletion resulted in low rates of tumor formation, tumor transplantation rate, and tumor growth in rats and mice when compared to well-fed control animals.[30,31] One of the early concerns in the development of antineoplastic chemotherapy was that it might exert an antitumor effect from a starvation mechanism rather than a direct tumoricidal effect of the drug.[30] More recently, the effects of protein depletion on tumor and host have been investigated using a variety of tumor models and experimental designs. Decreased tumor growth as a response to chronic protein malnutrition has been clearly demonstrated in four of these studies.[32–35] In three other studies in which rate of tumor growth and host survival have been investigated, the combination of decreased tumor growth and prolonged host survival compared to normally nourished TB control animals has been demonstrated.[36–38] One problem with these studies is that none of them report total food intake in detail, and most have been done with unbalanced orally fed diets. Since rats and mice frequently do not eat unbalanced diets or incomplete diets, and since total substrate depletion can have a profound effect on tumor growth,[4–10,16,17,30,31] it is difficult to know whether the diminished tumor growth obtained was due to total substrate deprivation or to the selective effect of nitrogen deprivation. These data reported in this study are unique in that the total food intake has been tightly controlled and the nitrogen intake has been varied over a wide range. The findings of diminished tumor growth and reasonable carcass composition at the 5% level therefore suggests a very specific effect.

The long-term effect on the host with a malignant tumor of a prolonged treatment with a low nitrogen diet is difficult to predict from available information. The usual clinical sequela of protein deficiency is the syndrome known as kwashiorkor, which consists of severe edema, low serum albumin concentration, fatty liver, total body potasium and magnesium depletion, and decreased plasma branched-chain amino acid concentration.[39] This is very different from the syndrome that occurs with protein and calorie depletion in which the primary features are severe wasting of both subcutaneous fat and muscle, which is the pattern usually observed with advanced malignancy. During this experiment, little evidence of either kwashiorkor or the protein calorie (marasmus) pattern of malnutrition was observed in any of the surviving animals, including those TB 5% animals in which decreased tumor growth was evident. There is, however, the very definite possibility that the kwashiorkor-like syndrome or other forms of malnutrition would develop in either TB rats or cancer patients maintained on low nitrogen diets over long periods of time. Development of these problems will depend upon the levels of nitrogen and energy given, amino acid composition of the nitrogen given, and the efficiency with which the normal adaptation mechanisms to low nitrogen intake function.[40] While these factors have been studied with regard to the prevention and treatment of starvation[39,41] and the determination of adequate levels of nitrogen intake for positive nitrogen balance,[42-44] detailed studies of nitrogen deprivation in cancer-bearing patients have not been reported. The animal work previously cited, however, does suggest that a survival advantage might occur under low nitrogen situations.[36-38] It should be mentioned that it is widely assumed that the host-tumor can compete more successfully than the host-carcass for nutritional substrate. This is based primarily on studies of an animal tumor system of glucose kinetics.[45] It should be stressed that it is only an assumption with regard to protein metabolism and tumor amino acid uptake and that this concept has never been carefully studied.

These data may be summarized as indicating that selective starvation of the host tumor has been accomplished by a nutritional manipulation, which has also resulted in reasonable preservation of host carcass. If these findings can be corroborated and extended with other animal work, they suggest a possible therapeutic approach to some patient populations with advanced tumor conditions.

Bronchobiliary Fistulas in Adults

J. GUGENHEIM, M. CIARDULLO, O. TRAYNOR, and H. BISMUTH

Reported herein are 16 cases of nontraumatic bronchobiliary fistula in adults observed over 32 years. The fistulas were due to either biliary obstruction or infectious diseases involving the liver. All patients had biloptysis and other respiratory symptoms, and most had cholangitis, jaundice, and/or sepsis. The diagnosis was established by fistulography or cholangiography. All patients except one were treated surgically by relief of biliary obstruction and drainage of intra-abdominal abscesses. All 15 surgically treated patients had a successful outcome. Rapid diagnosis and early treatment of septic complications are necessary, but careful assessment and surgical relief of the biliary obstruction are essential in successfully treating this condition.

BRONCHOBILIARY FISTULA is defined as the passage of bile in the bronchi and presence of bile in the sputum (biloptysis), the pathognomic sign of the lesion; bronchobiliary fistula usually occurs either in the congenital form or following thoracoabdominal trauma. However, it can also occur as a rare complication of diseases of the biliary tract. In this situation the fistula can be due either to obstruction of the bile ducts or to infectious diseases involving the liver (hydatid cysts, echinococcosis, or amebic abscess). Management of these fistulas is often very difficult and can be associated with high morbidity and mortality rates. Early recognition and proper management are essential to avoid a fatal outcome. In this report we outline our experience with 16 cases of acquired, nontraumatic bronchobiliary fistulas in adults.

Patients

Between 1954 and 1985, 16 cases of bronchobiliary fistula were referred to Hôpital Bichat (1954–1970, surgical service of Dr. Jacques Hepp) and Hôpital Paul Brousse, Paris, France. We have reviewed these patients with respect to clinical features, diagnosis, treatment, and results. Patients with pleurobiliary fistulas were excluded. There were eight women and eight men with a mean age of 41.4 years (range: 21–65 years).

From Service de Chirurgie Hépato-Biliaire et Groupe de Recherche de Chirurgie Hépatique, Hôpital Paul Brousse, Villejuif, France

Etiology (Table 1)

Associated iatrogenic injury of the bile ducts was present in eight cases. A postoperative stenosis of the bile ducts was present in five patients following cholecystectomy and in another patient following hepaticojejunal anastomosis for biliary carcinoma. Two other stenoses developed following gastrectomy and duodenopancreatectomy. In eight patients the main etiologic factor was chronic hepatic infection, but all these patients had previously undergone surgical intervention. Biliary obstruction was present in six of these patients, and in one this was clearly shown to be due to iatrogenic injury of intrahepatic bile ducts and in the other, to associated sclerosing cholangitis following injection of iodine solution in the bile ducts. Biliary obstruction was not demonstrated in one patient requiring reoperation for a recurrent hydatic cyst nor in the patient presenting with an amebic abscess.

Clinical Features

Respiratory symptoms, jaundice, and cholangitis were the cardinal clinical features of bronchobiliary fistula in this series. All 16 patients had bile in the sputum (biloptysis) and 11 of these patients gave a longer history of chronic irritable cough productive of greenish sputum. Seven patients presented with acute fulminating

TABLE 2. *Symptoms and Signs of Sixteen Instances of Bronchobiliary Fistulas*

Symptoms	No. of Patients
Biloptysis	16
Jaundice	14
Cholangitis	15
External biliary fistula	9
Subphrenic abscess	11

bronchopneumonitis and dyspnea. Jaundice was present in 14 patients and acute cholangitis occurred in 16 patients. Nine patients had an external biliary fistula. Finally, 11 patients had fever and right upper quadrant abdominal pain associated with subphrenic abscesses (Table 2).

Radiologic and Laboratory Investigations

Chest x-ray demonstrated a right lower lobe pneumonia in five cases (Fig. 1). However, it was often difficult to demonstrate the fistula itself before surgery. The most reliable way was to perform a fistulogram when an external fistula was present (nine cases) (Fig. 2). In two instances, percutaneous transhepatic cholangiography was useful (Figs. 3 and 4). An HIDA scan was performed in two instances and demonstrated the fistula in both cases. Bronchograms were done in three instances but demonstrated the fistula in only one case. In seven cases, after surgery T-tube cholangiography demonstrated the fistula (Table 3). Laboratory investigations always revealed leukocytosis, increased serum bilirubin levels, and sputum containing bilirubin and multiple microorganisms. In ten cases the same microorganisms were found in the bile.

Operative Findings

A total of 42 operations were performed on these 16 patients (range: 1–5 operations per patient) (Table 4). Of these operations, 14 were performed in other hospitals prior to admission to Bichat-Paul Brousse Hospitals. In our institution, treatment of the bronchobiliary fistulas necessitated 26 operations on the 16 patients (range: 1–3 operations per patient).

All of the fistulas were on the right side of the chest. In 11 cases, a subphrenic abscess was present. In one instance, a pleurobiliary fistula (due to percutaneous transhepatic cholangiography) was associated with the bronchobiliary fistula. Underlying diseases of the bile ducts and/or the liver have previously been described.

Treatment

Operation was carried out in all but one patient who was admitted to our institution at a late stage and in an extremely poor condition, which prevented any aggressive therapy prior to death. The primary goals of surgery were to treat biliary obstruction if this was present, and to drain all abscesses. Relief of biliary obstruction was required in all except two cases (one amebic abscess and one hydatid cyst). Biliary drainage procedures included Roux-en-Y hepaticojejunostomy (four patients), choledochoduodenostomy (one patient), T-tube stenting (six patients), and fistula anastomosis (two patients). Subphrenic abscesses were drained in 11 patients. Right lower pulmonary lobectomy was carried out in only one patient, although this procedure has been carried out in three patients before referral.

Outcome

No mortality rate was observed among the 15 patients who were operated on.

Case Reports

In order to emphasize the diagnostic and therapeutic problems encountered in patients with bronchobiliary fistulas, two illustrative case histories are presented.

Case 1

A 65-year-old female first presented in 1962 with attacks of right upper quadrant abdominal pain and was diagnosed as having cholelithiasis. No treatment was undertaken and she remained well until

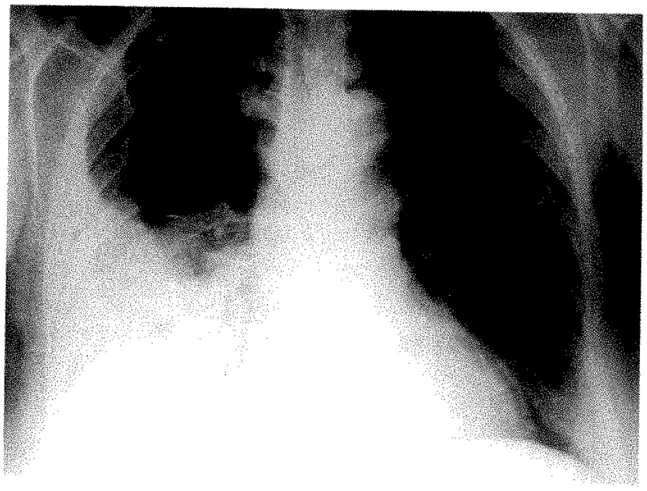

FIG. 1. Chest x-ray showing right lower lobe pneumonia.

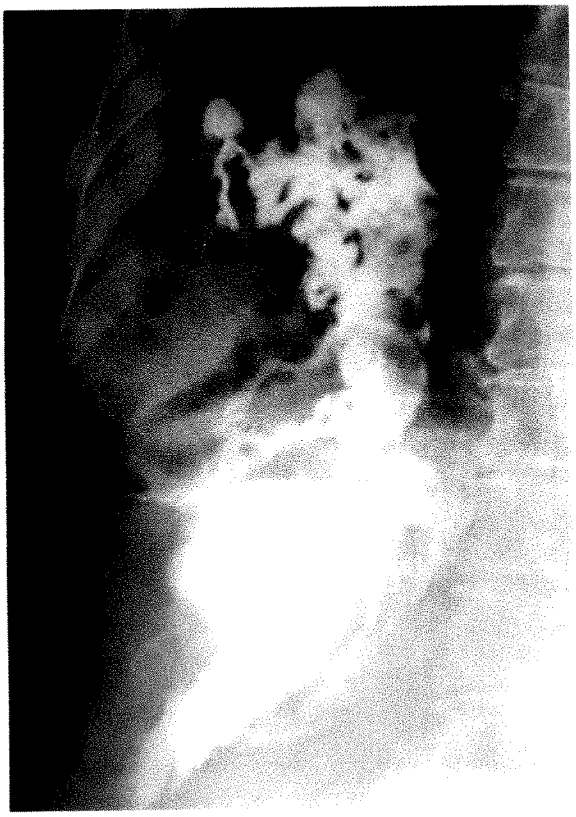

FIG. 2. Fistulogram showing large subphrenic abscess cavity communicating with the right bronchial tree. This patient had a postoperative stenosis of the bile duct following hepaticojejunal anastomosis for biliary carcinoma.

1972 when she began to have attacks of cholangitis. At that time cholecystectomy was undertaken and during surgery a sclerotic narrowing was found at the junction of the cystic duct and the hepatic duct. This area was excised and a hepaticoduodenostomy was performed. Nine months later she began to have further attacks of cholangitis with persistent cholestatic jaundice. A percutaneous liver biopsy in the posterior axillary line was performed and showed marked cholestasis with leucocytic infiltration but no evidence of fibrosis or cirrhosis. The biopsy was followed by a bile-stained pleural effusion and biloptysis. The pleural effusion was drained, which resulted in an external biliary fistula and biliopurulent discharge. She was then referred to this hospital with three problems: (1) recurrent cholangitis; (2) bronchobiliary fistula; and (3) external biliary fistula.

On admission she was jaundiced and in poor general condition, weighing 55 kg. She had hepatomegaly but no signs of hepatic insufficiency or portal hypertension. The white cell count was 23,000 and the liver function tests showed a cholestatic picture. A fistulogram showed a large abscess cavity, which was probably below the diaphragm. A percutaneous transhepatic cholangiogram displayed markedly dilated intrahepatic bile ducts with an obstruction just below the hilar confluence. Surgical exploration of the cavity was performed and three drains were inserted. At the same time an external biliary drain was inserted. After operation the abscess cavity regressed satisfactorily, but the bile drainage was irregular and unreliable despite several changes of drain. After 3 weeks the bile drainage stopped completely, and this was followed by septicemia and rigors. Surgical exploration was undertaken. A tumor of the common bile duct was found at the previous hepaticoduodenal anastomosis, and it was causing complete obstruction of the biliary tree. There were several stones above the stenosis. The tumor was completely excised and a hepaticojejunal anastomosis was performed, going up high on the left hepatic duct, and using a long Roux-en-Y loop. After operation the jaundice regressed satisfactorily and she was discharged with no further biliary problems. The histology confirmed a well-differentiated adenocarcinoma with widespread invasion of the submucosa and muscularis mucosae of the duodenum.

Case 2

A 43-year-old female was referred in 1984 for treatment of an external biliary fistula. In 1977, she had epigastric pains and hepatomegaly, and a surgical hepatic biopsy revealed steatosis. A second operation was undertaken 6 months later for a right subphrenic abscess. She was in good condition after surgery until January 1983 when she developed biloptysis. In March 1983 a thoracotomy was performed along with a pleural decortication, right middle pulmonary lobectomy, and suture of the bronchus. There was a 1.5 cm hole in the diaphragm that was also oversewn. External percutaneous hepatic biliary drainage was instituted during this operation. After surgery, the drain continued to yield bile, and the patient was referred to this hospital.

On admission on January 1984, she was in a poor general state and weighed 50 kg for 1.65 m. She was not jaundiced and had no signs of hepatic insufficiency or portal hypertension. She had a low grade pyrexia and a leucocytosis. Ultrasound examination of the liver showed a normal sized liver with aerobilia and no dilatation of the intrahepatic bile ducts. Fistulography showed opacification of the right biliary tree with narrowing of the right biliary duct and without opacification of the common bile duct. Percutaneous hepatic cholangiography showed dilatation of the left biliary branches. An ERCP was then performed; it revealed complete obstruction of the hilar confluence. Arteriography showed thrombosis of the right branch of the hepatic artery. A surgical

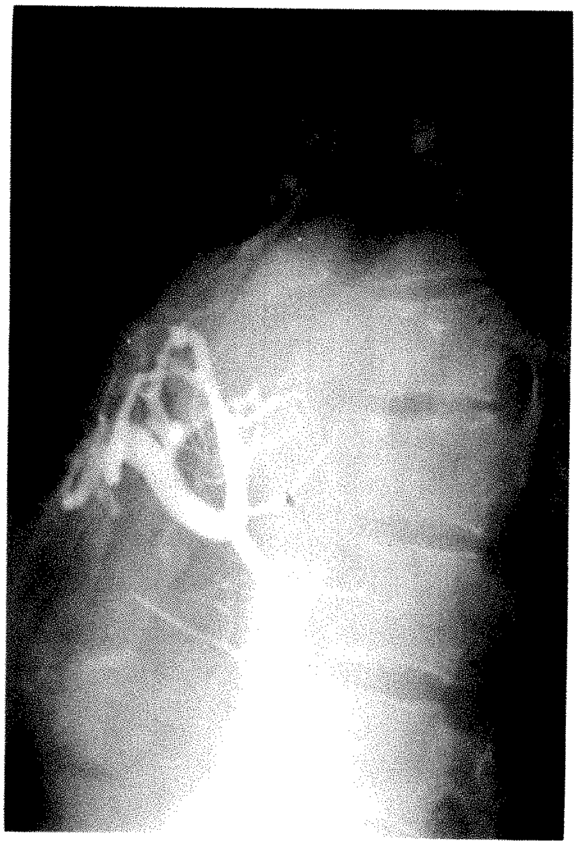

FIG. 4. Percutaneous transhepatic cholangiography (lateral view) from the same patient.

exploration was undertaken. The right lobe was hypertrophied, and there was left lobe atrophy. A stenosis of the primary bile duct confluence extending to the right secondary confluence was found, and there were several stones above the stenosis. An external biliary fistula and a biliodudenal fistula were also present. After dissection of the hilus, opening of the right and left biliary branches, and removal of the stones, a direct mucosa to mucosa anastomosis was performed between a Roux-en-Y loop of jejunum and the right primary hepatic branches. The left main hepatic duct was also included in the anastomosis. Two silastic biliary stent drains were placed across the anastomoses in the two right hepatic branches and exteriorized percutaneously via the Roux-en-Y loop.

Histologic examination showed fibrosis without any sign of neoplasia.

The postoperative course was uneventful, and she was discharged on the 16th postoperative day. On follow-up, she has remained well and has improved her state of nutrition. The drains were removed 18 months later and she has remained asymptomatic.

Discussion

Bronchobiliary fistulas are extremely rare, and we have not encountered the congenital forms[1,2] or bronchobiliary fistulas secondary to thoracoabdominal trauma[3,4]. The first description of a bronchobiliary fistula was that of Peacock in 1850 in a patient with a hydatid cyst.[5] In 1938, Ochsner described a 4% incidence of bronchobiliary fistulas in 453 pyogenic liver abscesses[6] and a 10.5% incidence of bronchobiliary fistulas in 3608 subphrenic abscesses.[7] According to Morton and Phillips,[8] the second leading cause of bronchobiliary fistulas other than hydatid, echinococcal, or amebic abscess of the liver is obstruction of the common bile duct. Thus, two major factors are responsible for the formation of bronchobiliary fistulas: mechanical (bile duct obstruction) and infectious (subphrenic or intrahepatic abscess). In the present study, iatrogenic stenosis was present in half the cases, although all but two of the remaining patients with hepatic infection had an associated obstruction of the bile duct. The nature of this obstruction was not always easy to define and in most cases probably resulted from the presence of severe inflammation close to the primary lesion or in the hilus of the liver. The obstruction of the bile duct is usually due to lithiasis,[9,10] hydatid cyst,[10-14] or postoperative stricture.[15-17] Less common reported causes are carcinoma of the head of the pancreas,[16] ascaris worm in the bile duct,[8] or tuberculosis.[18] Bile duct obstruction leads to cholangitis, intrahepatic abscess, and rupture of this abscess into the pleural space or, if adhesions exist, into the bronchi. This explains the preferential location of bronchobiliary fistulas in the right side of the chest. However, some exceptional cases of bronchobiliary fistulas located in the left side have been described.[19,20]

The diagnosis is usually made clinically by the presence of bile in the sputum. This biloptysis may occur either as an acute pneumonitis or as a chronic irritable cough productive of greenish sputum. In patients with a long history of biliary tract disease, diagnosis is usually easy. However, in some cases signs are minimal, for

example, cough with yellow sputum.[21] Sutherland et al.[22] have described false bile ptyalism in patients with sickle cell disease and hemolytic crisis. However, if this condition can be excluded, the presence of bile in the sputum is pathognomonic of bronchobiliary fistula.

Bronchoscopy and bronchography rarely demonstrate the fistula and are not essential for either diagnosis or therapy. If an external fistula exists, a fistulogram is the best way to visualize the fistula. In its absence, transhepatic cholangiography[18] or endoscopic retrograde cholangiography[23] may be used. Cholescintigraphy using^{131}I rose bengal has permitted peroperative diagnosis of thoracobiliary fistula,[24] but Hida or pipida cholescintigraphy with delayed views are probably more reliable in detecting small bronchobiliary fistulas.[25-27]

Prevention of these fistulas by early diagnosis and treatment of the underlying cause is extremely important since treatment of established bronchobiliary fistula is usually very difficult. These patients frequently have had several previous operations, and they are usually severely ill with sepsis, malnutrition, and respiratory problems. In the chronic form, it is often necessary to prepare the patient for operation by antibiotic therapy, hyperalimentation, and respiratory physiotherapy. However, in the acute fulminating form, an agressive and rapid approach is necessary. A two-stage approach can be used: (1) external biliary drainage by percutaneous or surgical drainage of subphrenic abscess and/or direct percutaneous drainage of the intrahepatic biliary tract; and (2) treatment of the underlying cause. In patients with biliary obstruction, the priority is treatment of the biliary disease. This is best achieved by a transabdominal approach[15,16] in order to relieve bile duct obstruction and to obtain adequate drainage of all abscesses. In all cases, peroperative cholangiography must be performed. In the case of postoperative strictures, a bilioenteric anastomosis should be carried out. We consider Roux-en-Y hepaticojejunostomy to be the best technique, although this may be difficult when the bile ducts are small, as is usually the case with this condition. In cases due to stones, removal of all stones and bilioenteric anastomosis must be performed.[9] The transthoracic approach should be reserved for those rare patients who have irreversible pulmonary and bronchial damage, or for patients with a traumatic bronchobiliary fistula without biliary obstruction. In this situation a primary transthoracic approach allows pleural decortication and repair of the diaphragmatic disruption.[28]

In conclusion, nontraumatic bronchobiliary fistula in adults is a rare condition complicating bile duct obstruction and/or liver abscesses. Rapid diagnosis and early treatment of septic complications are necessary, but surgical relief of the biliary obstruction following full and careful assessment is essential.

To evaluate changes of peripheral ketone body (KB) metabolism after operation, muscle metabolism in postsurgical patients was studied at 3 hours (S_I) and 24 hours (S_{II}) after surgery by the forearm catheter technique. Data were compared to those of equivalent fasted controls (C_I, C_{II}). In a manner consistent with enhanced mobilization of endogenous substrate stores, arterial concentrations of free fatty acids (FFA), 3-hydroxybutyrate (3-HOB), and acetoacetate (AcAc) were markedly elevated immediately after surgery. This increase was accompanied by a rise in muscular utilization of AcAc (S_I: 0.21 ± 0.05 μmol/100 g/min; C_I: 0.08 ± 0.05, $p < 0.05$) and 3-HOB (S_I: 0.24 ± 0.06 μmol/100 g/min; C_I: 0.11 ± 0.01, $p < 0.05$). Surprisingly, on the first postoperative day, concentrations of AcAc and 3-HOB fell below those of fasting controls. Concomitantly, the utilization rate of AcAc by muscle (S_{II}: 0.07 ± 0.03 μmol/100 g/min; C_{II}: 0.27 ± 0.04, $p < 0.05$) was significantly lower in patients than in controls. Reduction of the fractional extraction rate of AcAc (S_I: 38.4 ± 3.8%; S_{II}: 24.0 ± 6.1%, $p < 0.05$), as well as a net production of 3-HOB by muscle (S_{II}: −0.08 ± 0.05 μmol/100 g/min; C_{II}: 0.49 ± 0.13, $p < 0.05$) 24 hours after surgery indicated a reduced peripheral capacity for KB removal. Since this finding was related to a significantly higher rate of muscular glycerol production (S_{II}: −0.13 ± 0.03 μmol/100 g/min; C_{II}: −0.06 ± 0.02, $p < 0.05$), one may suggest that increased intramuscular availability of FFA from triglyceride hydrolysis was responsible for the impairment of peripheral KB utilization. These results indicate that KBs contribute little to energy metabolism in skeletal muscle tissue in the late postoperative phase.

KETONE BODIES (KBs) are important in mammalian metabolism, not only because of their role as substrates for energy metabolism, but also because of their regulatory function in the metabolism of several tissues. Thus, during periods of food deprivation, concentrations of KBs in blood (consisting mainly of 3-hydroxybutyrate [3-HOB] and acetoacetate [AcAc]) are significantly elevated above postabsorptive levels. Since ketones can serve as alternative energy-yielding substrates in brain, heart, kidney, and skeletal muscle, they reduce whole body glucose demand. Thus, gluconeogenesis and total body glucose turnover are attenuated.[1] Therefore, it was proposed that ketosis represents an important mechanism for conservation of body protein, since glucose production during fasting is primarily derived via gluconeogenesis from amino acids.[2]

In contrast to what is known about the fasting state, the physiologic role of KBs during postsurgical stress is only poorly understood. Following trauma or injury, an increased mobilization of endogenous fat stores occurs. This is known in healthy subjects to be followed by an increase in hepatic ketogenesis.[3] However, with the stress of surgery,[4] trauma,[5–7] or infection[5,8,9] the plasma concentrations of 3-HOB and AcAc remain low, even during caloric deprivation. Several investigators[10,11] have suggested that the lack of a ketotic response in surgical patients contributes to fuel deficiency in muscles and possibly to widespread protein catabolism. However, because of recent results[12,13] the possibility that KBs per se can preserve the amino acid pool, is questionable.

In addition, there are conflicting observations concerning the peripheral capacity for utilization of ketones following trauma or surgery. Whereas some authors re-

ported impaired removal of KBs,[8,14] others found a normal peripheral utilization of ketones according to their arterial supply.[5,15,16]

In the present study, the interrelationship between ketosis and peripheral KB utilization was investigated in the early and late postoperative periods, thus giving information on the dynamics of KB metabolism after surgery. Data were compared to those from fasting controls. By means of the forearm technique,[17] substrate metabolism of peripheral muscle tissue could be quantitated selectively.

Materials and Methods

Subjects

Two groups of normal subjects (C_I and C_{II}) and two groups of postsurgical patients (S_I and S_{II}) participated in the present study. Control subjects and patients were studied at different time points during a 36-hour fasting period, which was interrupted in patients by the surgical procedure. Detailed information on groups C and S is given in Table 1. Groups C_I and C_{II} consisted of ten (C_I) and five male (C_{II}) volunteers, recruited from medical students and the staff of the Munich University School of Medicine. None had a family history of diabetes mellitus, and a physical examination and laboratory tests excluded other diseases. All of the subjects consumed a weight-maintaining diet. Groups S_I and S_{II} consisted of 23 (S_I) and eight male (S_{II}) postsurgical patients, who were well matched by age and weight with the controls. All had undergone elective upper abdominal surgery for nonmalignant gallbladder and stomach diseases, and were within ±10% of ideal body weight before surgery. They had been in excellent health prior to surgery and did not exhibit glucose intolerance or hyperlipemia. None of the subjects received drugs known to alter glucose, insulin, or lipid metabolism. In all patients the postoperative course was uneventful. The nature, purpose, and possible risks involved in the study were carefully explained to all subjects and patients before seeking their voluntary signed consent.

Experimental Protocol

Protocols were reviewed and approved by the ethics committee of the German Research Council, corresponding to the Helsinki Declaration of 1975. Group C_I was studied after a 15-hour fasting period and group C_{II} after a 36-hour fasting period. During fasting, daily intake consisted only of at least 1500 mL of water; postsurgical subjects were fasted preoperatively for 10 hours. Metabolic measurements were performed in group S_I at 3 hours and in group S_{II} at 24 hours after surgery, thus corresponding in the duration of fasting to controls (C_I and C_{II}), if a mean duration of the surgical procedure of 2 hours is assumed. All patients received only saline infusion until metabolic measurements were completed.

Forearm Technique

As described originally by ANDRESS,[17] the forearm catheter technique represents an adequate method for investigation of metabolism in peripheral muscle tissue. The technique requires the simultaneous sampling of arterial and deep venous blood, together with the measurement of forearm blood flow. Thus, by means of a small teflon catheter (Vygon No. 11512, Vygon, Aachen, West Germany), a deep muscle vein of the forearm was cannulated in a retrograde manner. The patency was maintained by infusion of physiologic saline. A plastic cannula (Abbocath #18 gauge, Abbott, North Chicago, IL) was inserted into the radial artery and also perfused with saline solution. For metabolic measurements, arterial and deep venous blood samples were collected every 10 minutes throughout a 40-minute steady-state period. Forearm blood flow was measured by venous occlusion plethysmography. Flow determinations were taken after each blood sampling.

Analytical Procedures

Plasma insulin, glucagon, epinephrine, norepinephrine, glucose, lactate, pyruvate, free fatty acids (FFAs), 3-HOB, AcAc, glycerol, and blood oxygen concentration were measured as described previously.[9,18]

Calculations

Substrate concentrations of the four measurements at each time point were averaged to calculate substrate balances across muscle tissue. Substrate turnover by muscle was determined by multiplying the average forearm blood flow with arterio-deep venous concentration differences. Mean forearm blood flow was derived from several determinations at each time point. In order to quantitate the interrelationship between arterial substrate supply and substrate utilization by muscle, the extraction ratio (%E) was calculated by dividing the arterio-venous substrate concentration difference by the arterial substrate concentration.

Statistical Analysis

Data are expressed as the mean ± SEM. Statistical differences were tested by means of analysis of variance. A difference was considered significant if $p < 0.05$.

Results

In the immediate postoperative period, forearm blood flow corresponded to that of controls (C_I: 3.1 ± 0.1 mL/100 g/min; S_I: 2.9 ± 0.1). Twenty-four hours after surgery, however, forearm blood flow was significantly increased (C_{II}: 3.0 ± 0.1 mL/100 g/min; S_{II}: 4.5 ± 0.2 mL/100 g/min, $p < 0.05$).

As a sign of stimulated neuroendocrine response, arterial concentrations of glucagon, epinephrine, and norepinephrine were clearly elevated due to postoperative stress. In the first 24 hours epinephrine showed a moderate decline, whereas the concentration of glucagon rose significantly (Table 2). The increase in plasma insulin concentration after surgery indicated pancreatic B-cell stimulation by stress-induced hyperglycemia (Table 3).

Following surgery, the arterial concentrations of FFAs and glycerol rose significantly in comparison to those in fasting controls, reflecting accelerated mobilization of endogenous fat stores (Table 3). Subsequently, an increment of 3-HOB and AcAc concentrations over the normal fasting range could be observed. However, 24 hours after surgery arterial KB concentrations decreased to significantly lower levels when compared to those in corresponding controls.

In the postsurgical patients the plasma KB/FFA ratio also was significantly elevated 3 hours after surgery (S_I: 0.60 ± 0.08; C_I: 0.35 ± 0.06, $p < 0.05$) and decreased to 0.38 ± 0.07 (S_{II}) on the first postoperative day (significantly less then control value C_{II}: 1.91 ± 0.14, $p < 0.05$).

When compared to controls, utilization of AcAc by muscle rose significantly in the early postoperative period (C_I: 0.08 ± 0.01 μmol/100 g/min; S_I: 0.21 ± 0.05, $p < 0.05$; Fig. 1). This seemed to be due to an increased arterial supply of AcAc, since %E was similar in both groups (Table 4). Whereas net uptake of 3-HOB by muscle was simultaneously increased (C_I: 0.11 ± 0.01 μmol/100 g/min; S_I: 0.24 ± 0.06, $p < 0.05$), utilization of 3-HOB already appeared to be impaired at this time, as indicated by the reduced %E.

Twenty-four hours after surgery AcAc turnover by muscle was clearly reduced, compared to S_I (S_{II}: 0.07 ± 0.03 μmol/100 g/min, $p < 0.05$) and to corresponding controls (C_{II}: 0.27 ± 0.04 μmol/100 g/min, $p < 0.05$). In controls utilization of AcAc by muscle increased according to its arterial supply (%E remained unchanged); the decrease in AcAc utilization in the postsurgical subjects was more pronounced than could be expected from the reduced arterial supply since a simultaneous decrease of %E was observed. In addition, 24 hours after surgery a net production of 3-HOB by muscle occurred (S_{II}: −0.08 ± 0.05 μmol/100 g/min; Fig. 1) indicating greatly reduced utilization of KBs by muscle tissue at this time point ($p < 0.05$ *vs.* C_{II}: 0.49 ± 0.13 μmol/100 g/min). However, the uptake of 3-HOB in C_{II}, although higher than in C_I, occurred at a lower extraction ratio than in C_I, which points to a beginning impairment of peripheral KB removal also in the controls at this time point.

and C_{II}). On the other hand, muscle venous 3-HOB/AcAc ratio was significantly higher in S_I and S_{II}, being consistent with a more reduced mitochondrial state of skeletal muscle during the postoperative period.

At each time point a significant correlation between arterial concentration of AcAc and its arteriovenous concentration difference was found in controls, which indicated the predominant role of the arterial supply of AcAc for its muscular uptake (Fig. 2). Postoperatively, however, a similar correlation could only be observed 3 hours after surgery, whereas 24 hours after surgery this correlation could no longer be demonstrated, suggesting a change in intracellular AcAc utilization.

Concomitantly, muscular glycerol release became elevated in the postoperative period (S_I: −0.08 ± 0.02 µmol/100 g/min; S_{II}: −0.13 ± 0.03, $p < 0.05$), suggesting simultaneously increased intramuscular lipolysis (Fig. 3). Additionally, at each time point, glycerol release exceeded the control values from fasted subjects significantly (C_I: −0.05 ± 0.004 µmol/100 g/min; C_{II}: −0.06 ± 0.02).

Immediately after surgery glucose uptake by muscle was elevated (S_I: 1.18 ± 0.17 µmol/100 g/min; C_I: 0.90 ± 0.04, $p < 0.05$), which was presumably due to the increased arterial supply, since %E of glucose was comparable (S_I: 6.5 ± 0.5; C_I: 6.4 ± 0.1). However, we observed a simultaneous increase in peripheral lactate production (S_I: −1.03 ± 0.40 µmol/100 g/min; C_I: −0.39 ± 0.02, $p < 0.05$). Twenty-four hours after surgery glucose uptake by muscle declined again, amounting at this time to 0.57 ± 0.25 µmol/100 g/min (S_{II}), which was comparable to that in fasted controls (C_{II}: 0.76 ± 0.06 µmol/100 g/min).

Since the corresponding lactate production remained elevated in the patients (S_{II}: −0.84 ± 0.22 µmol/100 g/min; C_{II}: −0.49 ± 0.03, $p < 0.05$), the net amount of glucose taken up by muscle declined (S_{II}: 0.10 ± 0.18 µmol/100 g/min; C_{II}: 0.48 ± 0.08, $p < 0.05$), as could be calculated by comparing the rates of glucose uptake and of lactate and pyruvate release.

In the early postoperative phase oxygen consumption by muscle was slightly, but significantly, reduced as compared to controls (S_I: 0.17 ± 0.01 vol%/100 g/min; C_I: 0.21 ± 0.01, $p < 0.05$). Subsequently, this difference even increased further (S_{II}: 0.14 ± 0.03 vol%/100 g/min; C_{II}: 0.22 ± 0.03; $p < 0.05$). The corresponding arterial oxygen content, however, was comparable between patients and controls (Table 3).

Discussion

The post-traumatic/postoperative state is characterized by a set of metabolic responses. Catabolism of all substrate stores prevails, as orchestrated by changes in hormonal patterns (increase in plasma levels of catecholamines, corticoids, and glucagon), by immobilization and probably by circulating agents liberated from the site of injury. Thus, proteolysis, lipolysis, and glycogenolysis are accelerated and blood glucose increases due to enhanced hepatic glucose production. Simultaneously, body fuel oxidation shifts toward oxidation of fat, and glucose is being saved for increased demands of

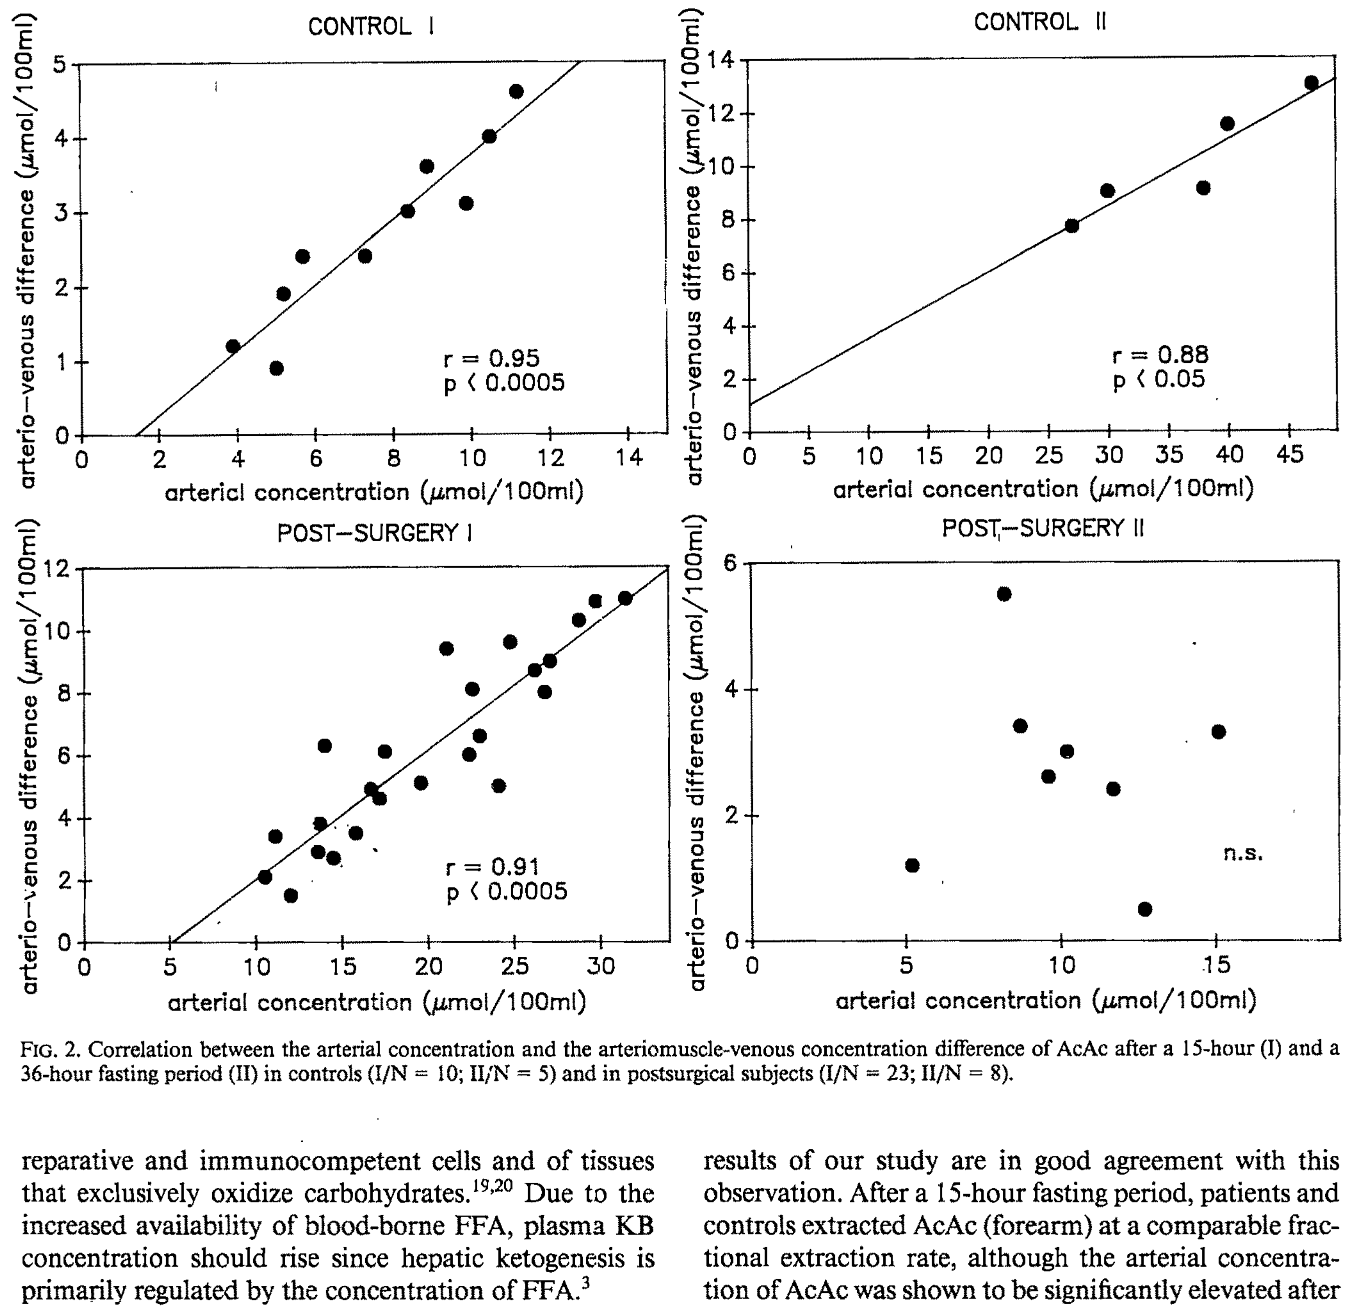

FIG. 2. Correlation between the arterial concentration and the arteriomuscle-venous concentration difference of AcAc after a 15-hour (I) and a 36-hour fasting period (II) in controls (I/N = 10; II/N = 5) and in postsurgical subjects (I/N = 23; II/N = 8).

reparative and immunocompetent cells and of tissues that exclusively oxidize carbohydrates.[19,20] Due to the increased availability of blood-borne FFA, plasma KB concentration should rise since hepatic ketogenesis is primarily regulated by the concentration of FFA.[3]

Our observations in the early postoperative phase are in line with this hypothesis. Three hours after surgery we found twofold to threefold higher levels of KBs compared to controls, following elevated concentrations of lipolytic hormones and FFAs. In the further postoperative course, however, KB concentration in postsurgical subjects significantly fell below that of controls. This well-described phenomenon is probably the result of the antiketogenic action of insulin,[21] alanine,[22] and possibly also of vasopressin[23] compounds, which are all known to increase after surgery.

It has been amply documented that in healthy persons the rate of KB utilization by muscle is directly related to their concentration in blood over a wide range.[1,24] The results of our study are in good agreement with this observation. After a 15-hour fasting period, patients and controls extracted AcAc (forearm) at a comparable fractional extraction rate, although the arterial concentration of AcAc was shown to be significantly elevated after surgery. In addition, a strong linear correlation was apparent between the plasma concentration and uptake of AcAc by muscle (Fig. 2). However, the extraction ratio of 3-HOB immediately decreased after surgery, indicating an impairment of 3-HOB utilization by muscle.

In the further course of fasting, the fractional extraction rate of AcAc and the strong linear correlation between concentration and uptake remained stable in the control subjects, while the arterial concentration of AcAc rose, a finding that is also confirmed by others.[25] On the other hand, in the late postoperative period a diminished extraction ratio for AcAc was observed; a linear correlation between concentration and uptake of AcAc by muscle could no longer be demonstrated (Fig.

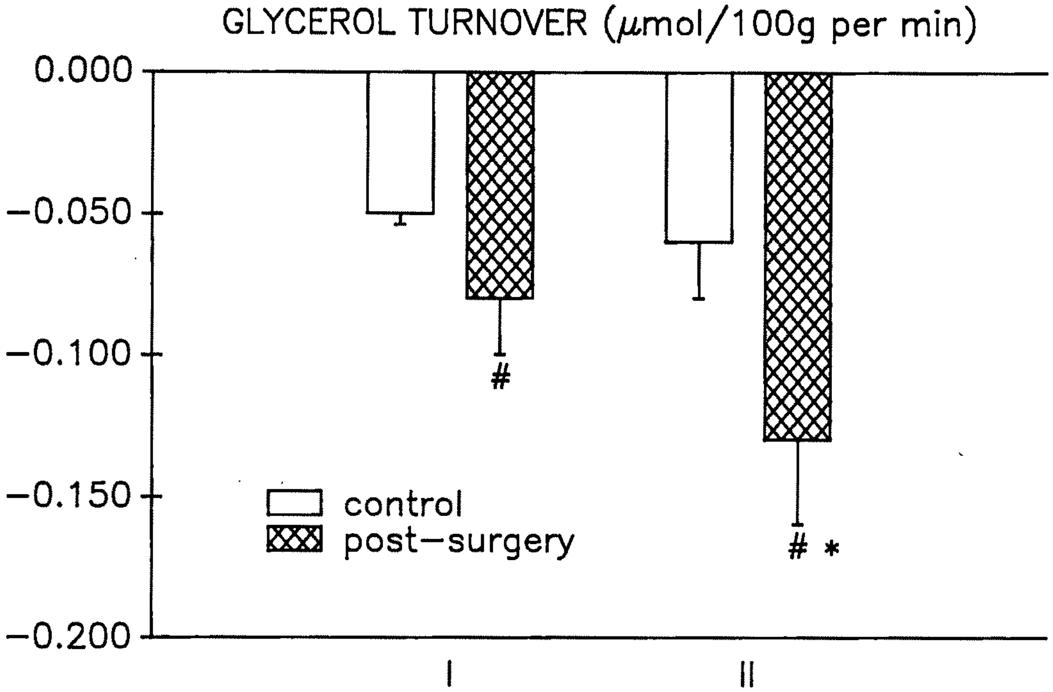

FIG. 3. Production of glycerol by muscle after a 15-hour (I) and a 36-hour fasting period (II) in controls (I/N = 10; II/N = 5) and in postsurgical subjects (I/N = 23; II/N = 8). *$p < 0.05$ *versus* I. #$p < 0.05$ *versus* controls. All values represent the mean ± SEM.

2). Even a net production of 3-HOB by muscle was seen at this time point, underlining the marked alteration of KB metabolism in muscle tissue under these conditions (Fig. 1). Taking into account the low rate of AcAc utilization, a net utilization of KBs was virtually absent. This and the markedly decreased net utilization of glucose pointed to the enhanced use of plasma FFA and of intramuscular substrate stores (fat, protein, glycogen) for energy fuels under these conditions.

The causal sequence of events leading to the peripheral poor assimilation of KB is not completely elucidated by the current studies. However, the potential impact of altered FFA metabolism upon utilization of ketones by muscle deserves further comment. Thus, in our patients we observed a rise in glycerol production by muscle following surgery that was even more pronounced on the first postoperative day, indicating enhanced degradation of muscle triglycerides.[26] Based upon the finding that in surgical patients, who depend mainly on lipid oxidation, combustion of tissue fat stores accounts for the bulk of fat oxidation,[27] the major part of hydrolyzed FFAs appears then to be transferred to mitochondria for beta-oxidation. As can be seen by the increased muscle-venous 3-HOB/AcAc ratio, postoperative skeletal muscle is characterized by a reduced mitochondrial redox state, possibly due to the enhanced beta-oxidation, which would expand the mitochondrial NADH pool.

Therefore, under these conditions, the intramuscular conversion of AcAc to 3-HOB may be strongly favored by shifting the equilibrium of the NADH-linked 3-HOB dehydrogenase reaction toward 3-HOB. In the presence of a rising intracellular concentration of 3-HOB, uptake of 3-HOB by muscle from the blood would decrease; this may explain the depressed extraction ratio of 3-HOB 3 hours after surgery.

However, the reduction of the fractional extraction rate of AcAc, as well as the finding of a net production of 3-HOB by muscle on the first postoperative day, is difficult to interpret by this hypothesis. An additional explanation would be that FFAs and AcAc share a common metabolic pathway, namely, formation of AcAc-CoA and acetyl-CoA.[28] A strongly stimulated degradation of FFA (with the resultant expansion of the AcAc-CoA pool) may directly impair utilization of blood-borne AcAc by inhibiting the reaction of AcAc-degrading enzymes.[1] Since under certain conditions, such as those in severe diabetes, during exercise, or after long-term starvation, KB can also be produced *de novo* in skeletal muscle tissue,[29-31] it cannot be excluded that this phenomenon also contributed to the observed decline in net consumption of KBs.

Consistent with our hypothesis is the fact that in diabetic ketoacidosis insulin administration increases the rate of KB utilization by muscle by inhibiting endogenous FFA release and oxidation.[30] On the other hand, the opposite effect can be produced by a catecholamine infusion into the forearm of diabetic patients, resulting in enhanced muscular glycerol output and a reduced extraction ratio of 3-HOB.[32]

Therefore, it is likely that also during postoperative stress, impairment of KB removal by muscle can be accounted for by the increased utilization of endogenous FFA as a muscle fuel. It appears that, with regard to the depressed KB utilization by muscle 24 hours after surgery, at least this amount of time is required for full stimulation of peripheral FFA utilization. This finding contrasts with the early increase in hepatic ketogenesis following elevation of plasma FFA.

In view of these data one is tempted to speculate about the physiologic importance of KBs and their roles in individual tissues during postsurgical stress. In carbohydrate-deficient states, such as those found after prolonged fasting, KBs may serve as signals of carbohydrate scarcity and initiate glucose sparing mechanisms in peripheral tissues. A similar situation can be assumed in the early postoperative phase when glucose requirements are rapidly increased by demands of reparative and immunocompetent cells and when peripheral combustion of fat alone cannot yet reduce oxidation of glucose sufficiently. During the further postoperative course, muscle tissue is able to substitute utilization of endogenous fat stores for utilization of KBs completely to meet energy requirements and to save glucose. In light of these findings the reduced KB production of the liver at this time may teleologically be reasonable. Furthermore, following severe surgical stress, exogenous KBs are not able to inhibit the overproduction of glucose,[15,33] nor do they exhibit a direct nitrogen-sparing effect.[12,13] Therefore, the development of ketosis in the late postoperative phase would not be anticipated to be as beneficial to the host as the ketosis of starvation.

Treatment of Dermatofibrosarcoma Protuberans with Mohs Micrographic Surgery

EDMUND R. HOBBS, M.D., RONALD G. WHEELAND, M.D., PHILIP L. BAILIN, M.D., JOHN LOUIS RATZ, M.D., RANDALL J. YETMAN, M.D., and JAMES E. ZINS, M.D.

Ten patients with dermatofibrosarcoma protuberans, all of whom had been treated previously by conventional excisional surgery without success, were treated with Mohs micrographic surgery. A team approach utilizing margin control by Mohs-trained physicians and reconstruction by surgical specialists was employed. Average follow-up exceeds 3½ years, with no recurrences. Microscopically controlled excision appears to be the treatment of choice for dermatofibrosarcoma protuberans.

DERMATOFIBROSARCOMA PROTUBERANS (DFSP) is an uncommon malignant tumor arising *de novo*[1] in the dermis, characterized by local infiltration and indolent progression. While rarely metastasizing,[2–4] this neoplasm is notorious for its propensity to recur even after wide excision. Recurrence rates in various series treated by wide excision are as high as 54%.[5] Current recommendations[1,3,6] call for excision of the tumor with a 3-cm or greater[7] margin of uninvolved skin and underlying fascia. Such generous margins are not possible in all cases, as when the tumor involves the face or distal extremities. Even when managed with wide excision, high recurrence rates of 10–20% have been reported.[3,6]

Since 1979, patients presenting to the Cleveland Clinic Foundation with DFSP have been managed jointly by the Departments of Plastic Surgery and Dermatology, using Mohs micrographic surgery (fresh tissue technique) and postoperative reconstruction. We wish to report ten cases of DFSP treated in this fashion, the largest such series to date. Thus far, no recurrences have been detected on periodic clinical follow-up.

From the Section of Mohs Histographic Surgery and Oncology, Department of Dermatology, and the Department of Plastic and Reconstructive Surgery, Cleveland Clinic Foundation, Cleveland, Ohio

Methods

In the treatment of large tumors using Mohs micrographic surgery (also called microscopically controlled excision or histographic surgery), the clinically apparent tumor is excised with a conservative margin. A map is drawn of the specimen showing the anatomic orientation of the excised tissue. The specimen is then divided into smaller segments suitable for frozen section processing, and the edges of each smaller segment are color-coded with dyes. These markings are recorded on the anatomic map and can be visualized histologically. Thus, with the Mohs surgical technique the precise anatomic location of each piece can be determined. Horizontal sections are then cut from the bottom of each piece for histologic analysis. For segments located on the periphery of the excisional specimen, a slightly tangential section is cut, establishing a continuous plane from the surface at the edge to the deepest portion of the segment on its interior aspect (Fig. 1). The frozen sections are then stained with hematoxylin and eosin in the routine manner.

This procedure allows the surgeon to simultaneously view the deep and lateral margins of the peripheral segments, as well as the deep margins of the interior segments. This aspect of Mohs surgery, together with the meticulous mapping procedure, constitutes the essential difference from standard margin control and yields significantly higher cure rates.[8] Because the entire margin is examined in this method, residual tumor is precisely identified. The surgeon marks the location of any residual tumor on the map, then returns to the patient to

remove additional tissue from those exact sites where the margin was positive for tumor. The procedure is repeated in this fashion until no tumor is detected. At this point the wound can be repaired as any other surgical wound. Such precise margin control allows the surgeon to minimize the ultimate size of the wound and yet be more assured of achieving a cure.

As an additional check in this series of patients, pathologic specimens from each case were submitted to board certified dermatopathologists for independent corroboration of the diagnosis.

Case Report

In 1975 a 30-year-old black man (Case 2) had a DFSP of the upper-mid back excised by his local physician, and then received 1000 rads of superficial x-ray to the area after operation. Five years later, a 3-cm diameter tumor was discovered adjacent to the surgical scar. Over a 2-week period, the patient underwent three wide excisions. Upon review of permanent sections after each of the first two of these procedures, margins were found to be involved with tumor. On the third excision, standard margins were clear. Five months later, however, he again noted a new 2.8-cm diameter nodule adjacent to the scar (Fig. 2), and was referred to the Cleveland Clinic Foundation. The patient then underwent Mohs micrographic surgery under local anesthesia. DFSP (Fig. 3) filled all four segments of the initial excision (Fig. 4). A second stage, wider and deeper than the first, revealed tumor in six of ten segments (Fig. 5). A third stage excised from these areas disclosed tumor in one of nine segments (Fig. 6). A fourth excisional specimen in the area of persistent involvement revealed no tumor in either of its two segments (Fig. 7). The resulting 5.5 × 6.4 cm defect (Fig. 8) was closed primarily. The patient has remained free of tumor in 6 years of follow-up.

Results

The case histories of the 10 patients with DFSP treated with Mohs micrographic surgery at the Cleveland Clinic Foundation are summarized in Table 1. Eight patients were male, and all but one (case 1) were less than 37 years old at the time of onset of their disease. Eight patients were Caucasian, one Black, and one Oriental. Seven tumors occurred on the trunk, one on the scalp, one on the cheek, and one on the thumb. All ten patients had been treated with excisional surgery prior to presentation with an average of two prior excisional surgical treatments each, excluding biopsies. Median duration of illness prior to referral for Mohs surgery was 5 years. Six were referred because of recurrence, while four (cases 5, 7, 9, and 10) were referred because of failure to achieve clear margins at surgery.

Seven patients were treated under general anesthesia and three under local. An average of three Mohs stages (excision iterations) per patient was required. Muscle was invaded by tumor in four of the ten cases (cases 5, 6, 7, and 10). In two cases (cases 5 and 7), the tumor extended to periosteum but did not involve bone. Two patients were allowed to heal by second intention, two wounds were closed primarily, two received split-thickness skin grafts alone, and four were repaired by combinations of split-thickness grafts with flaps or partial primary closure.

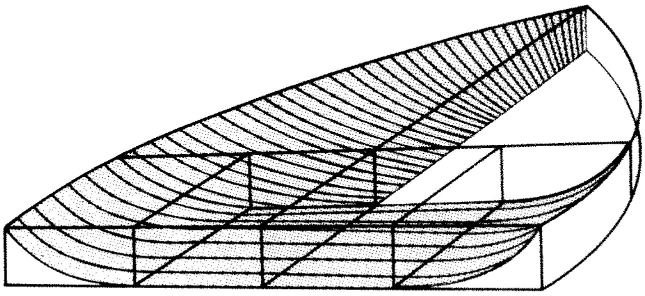

FIG. 1. Sections from each excisional specimen component are cut in such a fashion that a continuous plane is established around the tumor. The pliable nature of fresh tissue allows it to be compressed and stretched as needed to establish planes of section that would not be possible were the tissue rigid.

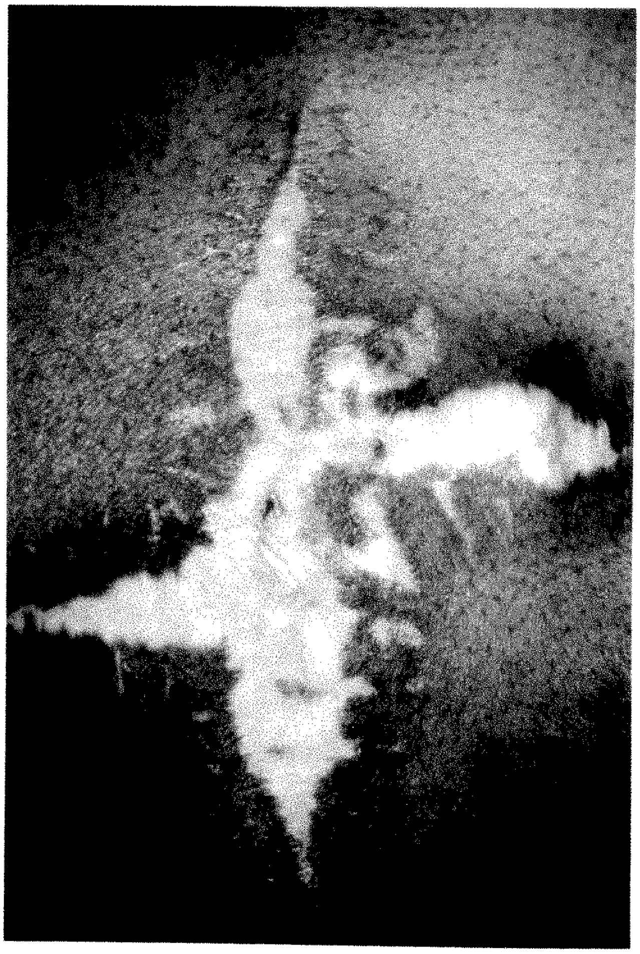

FIG. 2. A 2.8-cm diameter nodule of recurrent DFSP is located between the vertical and upper right arms of the old scar on the mid upper back.

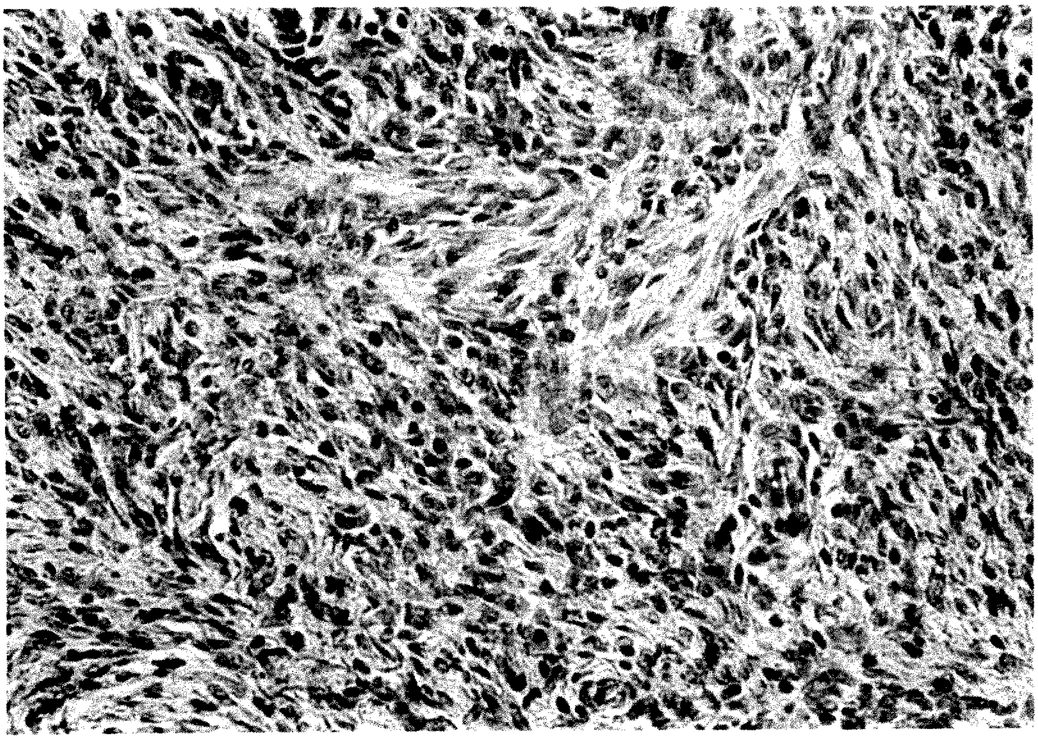

FIG. 3. DFSP is characterized by a storiform pattern of interlacing bands and whorls of fibroblasts, often forming cartwheel-like arrays (hematoxylin and eosin) (original magnification × 20).

The average duration of follow-up in this series of patients is 43 months. Median follow-up duration is 38 months (range: 15–91 months). To date, no evidence of recurrence has been found in any of these patients.

Discussion

DFSP is an unusual tumor, the incidence of which has been estimated at 0.8 cases per one million persons per year.[1] It usually appears in the second through fifth decades,[9,10] but can occur at any age.[4] Most series report a slight male preponderance.[1,6,10] The lesion is most commonly located on the trunk or proximal extremities, but can occur in any location.[4]

Clinically, the lesion appears initially as a dusky indurated plaque, the significance of which is often dismissed by both patient and physician. A history of antecedent trauma is often obtained.[4] The tumor may be

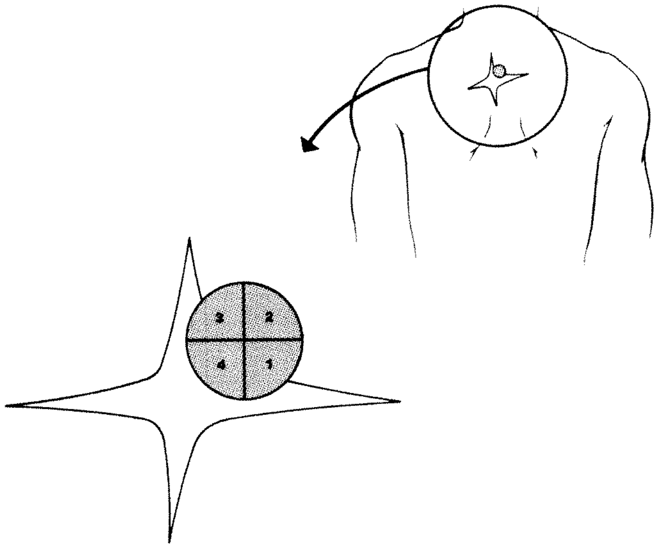

FIG. 4. The stylized Mohs map is shown, with colored dye codings omitted for clarity. All four segments of the initial excision were filled with DFSP, as indicated by shading.

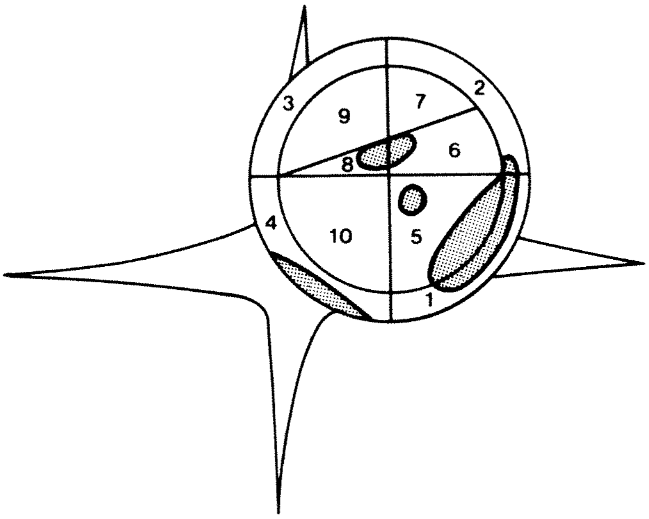

FIG. 5. The second excision was wider and deeper than the first, and disclosed tumor at the margin in six of ten segments.

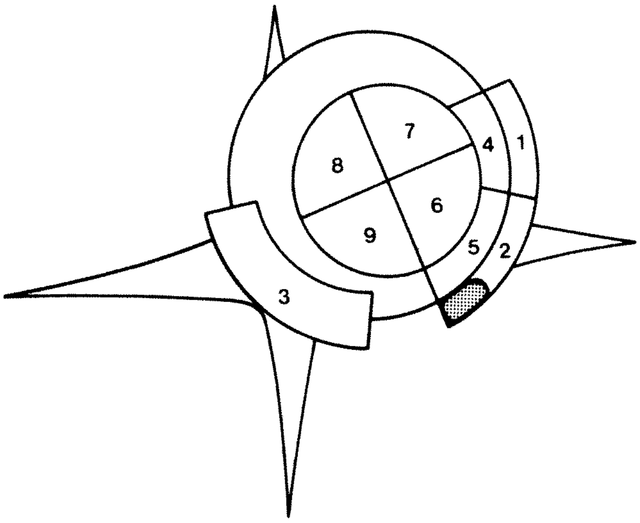

FIG. 6. The third excision, restricted to the areas positive for tumor in the second, revealed tumor at the margin in one of nine segments.

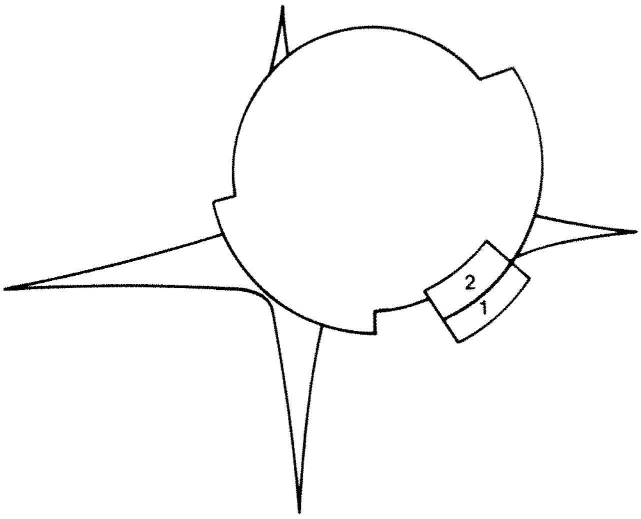

FIG. 7. The final excisional specimen was free of tumor in both segments processed.

flesh-colored, bluish-red, reddish-brown, or yellow in color. In time, sometimes decades, the tumor develops a nodular or multinodular quality and may become symptomatic and ulcerate. Neglected lesions may be quite large, as great as 20 cm in diameter[1,10] clinically, but even large tumors are usually not bound down to underlying noncutaneous structures. In advanced stages, the tumor may invade fascia and muscle. While pulmonary and nodal metastases do occur,[6,7,11] such biologic behavior is rare. The incidence of metastases has probably been overestimated by virtue of the inadvertent inclusion of tumors now defined as malignant fibrous histiocytoma[2] or other soft tissue malignancies[4] in older series reporting metastatic DFSP.

Histologically, DFSP is characterized by a storiform pattern created by spindle-shaped cells arranged in cartwheel-like arrays about collagenous centers.[4] The interlacing bands and whorls of fibroblasts often fill the entire reticular dermis and extend into subcutaneous fat. The center of DFSP tends to be more cellular than the pe-

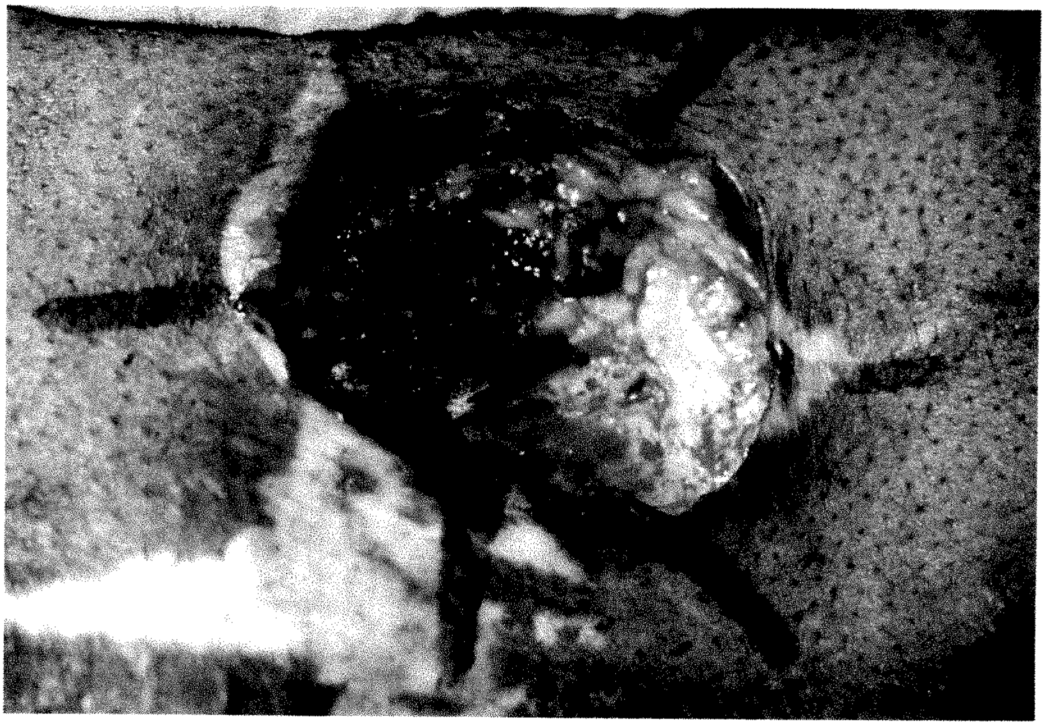

FIG. 8. The final operative defect measured 5.5 × 6.4 cm and was closed primarily.

TABLE 1. *Summary of Cases*

Case No.	Age at Mohs Surgery (yr)	Tumor Location	No. of Prior Excisions (Excluding Biopsies)	Repair	Months of Follow-up

* Split-thickness skin graft.

riphery, where cells appear more mature and are associated with collagen.[4] Large numbers of mitotic figures are usually not seen, nor is cytologic atypia usually found. While the cellular origin of this tumor remains controversial, evidence favors the fibroblast.[12]

The nodular quality of DFSP gives the clinician an erroneous impression of circumscription,[4,12] which results in frequent treatment failures. The main body of the tumor gives off multiple pseudopod-like projections of neoplastic cells, which may extend 3 or more cm beyond the tumor proper, infiltrating between normal collagen bundles both laterally and deep. These finger-like projections of tumor are microscopic in size and cannot be appreciated clinically. For the same reason, these extensions can be missed by any histologic sectioning technique (including vertical step sectioning) that does not examine the entire undersurface and lateral margins of the excisional specimen. Failure to excise all of these projections is presumed to be the major reason for the high rate of recurrence noted with this tumor.[10]

In 98 cases studied by Taylor and Helwig, a 49% rate of recurrence was found, nearly 40% of which recurred during the first year and 75% within 3 years following surgery.[4] In Hajdu's series of 119 cases, 54% recurred after wide excision, most within the first year. Of 17 cases treated by Pack and Tabah,[10] 24% recurred. Similarly, one fourth of those treated by Burkhardt et al.[9] recurred. Rowsell et al.[13] reported five cases, all of which had to be returned to surgery when margins were found to be involved. Two of these patients required two additional surgical procedures each, and one patient required three additional surgical procedures, in spite of the authors' technique of taking an average 2.7 cm margin of clinically uninvolved skin and subcutaneous tissue at the first re-excision.

McPeak et al.[6] reported an 11% recurrence rate in 27 patients treated with a 3-cm margin of clinically uninvolved skin, down to and including fascia. Seventy-five per cent of the recurrences in their overall series of 86 patients was noted in the first 2 years. Roses et al.[3] used 3-cm margins in ten patients and reported a 20% recurrence rate, while Bendix-Hansen et al.[1] took 3-cm margins in seven patients and had no recurrences.

While recurrences are usually noted within 3 years,[3,4] late recurrences have been noted at 19 years[10] and 20 years.[4] However, although late recurrence is uncommon, this phenomenon must be kept in mind when assessing the efficacy of any proposed treatment for DFSP.

Mohs micrographic surgery was devised more than 50 years ago by Frederic E. Mohs, M.D. at the University of Wisconsin.[8] In Mohs' original fixed tissue technique, a chemical paste of zinc chloride was applied to cancerous tissue *in situ,* and subsequently the tissue was excised bloodlessly, mapped, and processed utilizing horizontal frozen sections to achieve total margin control. While the fixed tissue technique is still used in selected applications[8] today, such as highly vascular tumors, bone tumors, or neoplasms with higher metastatic potential, it has largely been replaced since the early 1970s by the fresh tissue technique, which does not utilize zinc chloride paste.

Mohs micrographic surgery is well suited to the treatment of neoplasms that tend to invade aggressively but locally, and have low rates of metastasis. Its most frequent application is in the treatment of recurrent basal cell carcinomas, large or morpheaform primary basal cell carcinomas, and midfacial or periauricular basal cell carcinomas. It is also useful for squamous cell carcinoma and squamous cell carcinoma *in situ,* sebaceous carcinoma, microcystic adnexal carcinoma, cutaneous adenoid cystic carcinoma, Merkel cell tumors, malignant fibrous histiocytoma, and extramammary Paget's disease.

The precise margin control made possible by Mohs surgery enables the removal of microscopic-sized extensions of tumor while conserving the maximum possible amount of normal tissue. It eliminates the guesswork inherent in excising tumors by arbitrary margin guidelines, such as the 3-cm guideline previously recommended for DFSP.[3] This advantage is especially appreciated when the tumor is located on or near functionally or cosmetically important structures such as the hand or face. Furthermore, the confidence generated by total margin control permits definitive plastic repair immediately upon conclusion of the Mohs procedure. This tissue-sparing feature also allows the use of wound repairs that would not be possible if the lesion were excised with 3-cm or greater margins, which typically necessitates split-thickness skin grafts.[6] The tissue conservation permitted by Mohs surgery even permits some smaller wounds to be closed primarily or to be allowed to heal by second intention.

Our team approach capitalizes on the margin control capabilities of Mohs-trained physicians and on the operative talents of surgical specialists. Small primary tumors can be excised, checked for positive margins, and repaired under local anesthesia in the outpatient surgical suite. The inpatient operating room and general anesthesia are utilized when indicated to eliminate the discomfort of local anesthesia, to reduce the risks of lidocaine toxicity, and to make use of monitoring and fluid replacement capabilities. In this setting, the Mohs surgeon can assist the surgical specialist by orienting and mapping excised tissue, and by rapidly checking all margins histologically with the Mohs technique. This modification of the traditional Mohs procedure has been shown to conserve valuable normal tissue in the surgical treatment of cutaneous tumors of the head and neck.[14]

Some authors have remarked that soft tissue neoplasms can be more difficult to read histologically with tissue processed using frozen sections.[12,15] Like Peters et al.,[16] we have experienced no difficulty in differentiating benign tissue from that involved with DFSP on standard Mohs sections.

To date, there are no reported instances of recurrence of DFSP following Mohs micrographic surgery. Mohs himself reported[17] five cases treated by the fixed tissue technique and two by the fresh tissue technique, all without recurrence after more than 5 years. Robinson reported four cases treated by the Mohs technique, with no recurrence after 5 years of follow-up.[12] Peters et al.[16] excised a facial DFSP with a modification of the Mohs procedure and had no recurrence 3½ years later.[18] Hess et al.[18] treated a myxoid DFSP of the chest with Mohs micrographic surgery and had no recurrence at follow-up 18 months later. Mikhail and Lynn[19] used Mohs surgery in two cases and had no recurrence in either more than 5 years later.[12]

The unusually high percentage of cases with muscle invasion (40%) reported here reflects an advanced state of disease in this series of patients having persistent or recurrent tumors. Given the possibility of late recurrence, it cannot be stated with absolute certainty that a cure has been effected in any of these cases. However, our average and median follow-up durations of 43 and 38 months, respectively, now exceed the 3 years, that constitute the period of greatest likelihood of recurrence.[3,4,6] Because of its inherent ability to spare normal tissue and yet to completely eradicate the tumor, Mohs micrographic surgery appears to be the treatment of choice for DFSP.[18,20]

Antibiotic Use During Major Head and Neck Surgery

JONAS T. JOHNSON, M.D.* and VICTOR L. YU, M.D.†

From the Department of Otolaryngology, University of Pittsburgh School of Medicine, Division of Head and Neck Oncology and Immunology, Eye and Ear Hospital of Pittsburgh, Pittsburgh, Pennsylvania, and the Department of Infectious Disease, University of Pittsburgh School of Medicine and the Veterans Administration Hospital, Pittsburgh, Pennsylvania†*

The appropriate use of prophylactic antimicrobial therapy in patients undergoing major contaminated surgery is an important issue for the head and neck surgeon. A series of five sequential, prospective, randomized, double-blind clinical trials of antibiotics for patients undergoing major contaminated oncologic head and neck surgery are reviewed and summarized. The information generated from the study of these 547 patients indicates that a number of drugs or drug combinations have similar efficacy when employed in adequate dosage. The bacteriologic spectrum of the prophylactic drug should include oral microflora, especially anaerobic bacteria. The administration of antibiotics effective against gram-negative aerobic bacteria may be unnecessary. Perioperative antibiotic administration should be initiated prior to surgery. To date, no evidence exists to support prolonged administration of antibiotics beyond the first 24 hours following surgery.

SURGEONS HAVE RELIED upon the administration of perioperative antibiotics to help reduce the incidence of postoperative wound infection. In a landmark study, Burke[1] demonstrated that the administration of antibiotic is maximally effective in preventing bacterial invasion when the antibiotic is administered prior to bacterial contamination. Administration of antibiotic 3 or more hours after bacterial contamination was ineffective in preventing bacterial invasion. This principle has been confirmed in human studies and is accepted today.[2-5]

The issue of prophylactic antimicrobial therapy for patients undergoing major head and neck surgery continues to produce some confusion. As a result, we present a brief review of recent clinical trials from our institution, which addresses issues of relevance to the surgeon. In a series of prospective, randomized clinical trials conducted in patients undergoing major oncologic head and neck surgical procedures, we have attempted to better define the spectrum of antimicrobial agents that have efficacy in preventing postoperative wound infections and to determine the optimal duration that these agents should be administered.

When contamination with oropharyngeal secretions does not occur, antibiotics are not required in patients undergoing major head and neck procedures. Clean procedures, such as thyroidectomy, parotidectomy, submandibular gland excision, or isolated radical neck dissection, are associated with postoperative wound infection of less than 2%.[6] Administration of antibiotic prophylaxis under these circumstances has not been demonstrated to reduce the risk of postoperative wound infection.

On the other hand, when major head and neck surgical procedures are contaminated by exposure to oropharyngeal secretions, the risk of a postoperative wound infection significantly increases. Wound infection rates of 28–87% have been reported.[7,8] This broad range may reflect variations in the magnitude of the procedures undertaken and differences in the definition of postoperative wound infection. It is now agreed that administration of perioperative antibiotics to patients undergoing contaminated head and neck procedures is required. In a prospective, randomized, placebo-controlled trial, seven of nine patients (78%) receiving a placebo from our institution developed a postoperative wound infection.[5]

Methods

These clinical trials were undertaken in a prospective, randomized, and double-blind fashion. Only patients

scheduled to undergo contaminated (skin to mucosa) oncologic surgical procedures were eligible. Patients undergoing transoral procedures or procedures in which the skin was not closed (*e.g.*, maxillectomy or planned fistula) were ineligible. During the course of the surgical procedure, the standard tenets of surgical antisepsis were followed and no major break in antiseptic technique occurred. Prior to randomization, patients were stratified by computer for factors that potentially affect the incidence of postoperative wound infection. These parameters included stage of disease (stage IV *vs.* stage III or less), timing of tracheotomy (anticedent tracheotomy *vs.* concurrent tracheotomy), exposure to radiation therapy (prior radiation *vs.* no radiation therapy), closure technique (primary closure *vs.* myocutaneous flap reconstruction), and surgical procedure (laryngectomy *vs.* other head and neck procedures).

Antibiotic Study I

In our first study, patients were randomly assigned to receive cefazolin (Kefzol®) alone (500 mg) *versus* clindamycin (Cleocin®) (600 mg) plus gentamicin (1.7 mg/kg).[9] The study regimen was administered intravenously 1 hour before operation and continued after surgery three times a day for either 1 or 5 days postoperatively.

Antibiotic Study II

The second study evaluated the efficacy of third-generation cephalosporin antibiotics in the prevention of postoperative wound infections.[5] Patients were randomly assigned to receive either cefoperazone (Cefobid®) (2 g), or cefotaxime (Claforan®) (2 g). This study was placebo-controlled. In each case, the study drug was administered intravenously 1 hour prior to surgery and continued every 8 hours for a total of four doses. The last drug administered was at 24 hours after surgery.

Antibiotic Study III

Prospective, randomized trials in other surgical fields have not consistently demonstrated increased efficacy of third-generation cephalosporins when compared to first-generation cephalosporins in the prevention of postoperative wound infection.[10–14] We theorized that the observed lack of efficacy of cefazolin in prophylaxis in our initial antibiotic trial may have been dose related in that the 500 mg dose may have been inadequate. Therefore, a second cefazolin trial was developed.[15]

Patients were randomly assigned to receive cefazolin (Kefzol®) (2 g) or moxalactam (Moxam®) (2 g). Once again, all antibiotics were begun 1 hour before operation and continued every 8 hours for a total of four doses.

Antibiotic Study IV

Gram-negative aerobic bacteria are frequently isolated from secretions obtained from postoperative head and neck wound infections. This is paradoxical in that gram-negative aerobic organisms are not normally inhabitants of the mucosal surfaces of the upper aerodigestive tract. To determine if the observed gram-negative aerobic bacteria were merely colonizing, preexistent wound infections rather than pathogenic, we undertook another study.[16] Patients were randomly assigned to either clindamycin (600 mg) *versus* clindamycin (600 mg) plus gentamicin (1.7 mg/kg). Clindamycin is active against gram-positive *cocci* and anaerobic bacteria, but not aerobic gram-negative *bacilli.* Thus, the clindamycin alone regimen lacked coverage against aerobic gram-negative *bacilli,* a notable omission when compared to previously established regimens of cephalosporin agents. In each case, antibiotics were administered intravenously beginning 1 hour preoperatively and continued every 8 hours for four doses (1 day).

Antibiotic Study V

It was speculated that longer duration of antibiotic administration may be a factor for a small subpopulation of patients undergoing major head and neck surgery. In our experience, patients at greatest risk for postoperative wound infection were those patients undergoing pectoralis major myocutaneous flap reconstruction after resection of an advanced stage carcinoma. To test the hypothesis that this subgroup of patients undergoing flap reconstruction would benefit from prolonged administration of antibiotics, another study was developed for patients in whom pectoralis major myocutaneous flap reconstruction was anticipated.[17] In a multi-institutional, prospective randomized trial, these patients were randomized to cefoperazone (2 g) for either 1 or 5 days postoperatively. In each case, the antibiotic was initiated 1 hour preoperatively and continued every 12 hours for the duration of the study. Patients randomized to 1 day of antibiotic received placebo on days 2, 3, 4, and 5.

Results

Antibiotic Study I

One hundred seven patients were randomized into this study. Wound infection developed as follows: cefazolin, one day (33%); cefazolin, five days (20%); clindamycin plus gentamicin, one day (7%); clindamycin plus gentamicin, five days (4%). These data demonstrated a statistically significant advantage using the drug combination clindamycin plus gentamicin *versus* cefazolin alone. The rate of postoperative wound infection for the patients receiving antibiotic for five days was not signifi-

TABLE 1. *Effect of Drug and Dose on Wound Outcome*

Drug	Dose	No. of Doses	Patients	Infections (%)	p Value
Placebo	—	—	9	7 (78)	<0.001
Cefazolin	500 mg	4	21	7 (33)	<0.05
Cefazolin	2 g	4	59	5 (8.5)	
Clindamycin	600 mg	4	52	2 (3.4)	
Clindamycin	600 mg	—	—		
Gentamicin	1.7 mg/kg	4	81	4 (4.9)	
Cefoperazone	2 g	4	39	4 (10)	
Cefatoxime	2 g	4	32	3 (9)	
Moxalactam	2 g	4	59	2 (3.4)	

cantly different from the patients receiving antibiotic for one day ($p > 0.05$).

Antibiotic Study II

Eighty-seven patients were enrolled. Wound infection developed in seven of nine patients (78%) assigned to placebo. This arm of the study was subsequently closed. Three of these patients experienced bacteremia. In each case, the organism identified was an anaerobic bacteria that was simultaneously identified in material taken from the wound.

Wound infections were encountered in 10% and 9.4% of patients receiving cefotaxime and cefoperazone, respectively. The observed rate of wound infection was not statistically different from the infection rate observed in patients receiving clindamycin plus gentamicin.

Antibiotic Study III

One hundred eighteen patients were enrolled. Wound infections were seen in five patients (8.5%) receiving cefazolin and two patients (3.4%) receiving moxalactam. These differences were not statistically significant ($p > 0.05$).

Antibiotic Study IV

One hundred four patients were enrolled. Wound infection occured in only two patients (3.4%) receiving clindamycin alone and in two patients (3.4%) receiving clindamycin plus gentamicin.

Antibiotic Study V

One hundred forty-two patients were enrolled 109 of whom underwent flap reconstruction as anticipated. The majority of the remaining 33 patients did not undergo flap reconstruction as a result of intraoperative evaluation.

Fifty-three patients received one day of antibiotic prophylaxis. Infection developed in 10 (18.9%). Postoperative wound infection developed in 14 of 56 (25%) of patients who received 5 days of perioperative prophylactic antibiotics ($p > 0.05$).

Conclusion

The combined results of five prospective, randomized, and double-blind clinical trials undertaken in 547 patients undergoing major contaminated oncologic head and neck surgery can serve as a basis for rational decision-making in this controversial arena.

First, it appears that a number of drugs or drug combinations (Table 1) may have similar efficacy in the prevention of postoperative wound infection when administered in adequate therapeutic dosage. We caution that while these studies do not show significant differences among the agents used, these data do not necessarily indicate that these agents are of equal value. Studies with much larger sample sizes would be required to satisfy the statistical requirements for such a claim.

Second, the spectrum of antibiotics used for oncologic head and neck surgery must include that of anaerobic microflora of the oral cavity. The most important group of oropharyngeal anaerobic bacteria that are potential pathogens include *fusobacterium, bacteroides,* and *peptostreptococcus* species. While the issue of coverage against aerobic gram-negative bacteria is not definitively settled, it appears that routine prophylactic coverage for these organisms is not necessarily indicated.[7,11]

Third, these data fail to demonstrate improved efficacy for antibiotics administered greater than 24 hours after operation. This observation is in keeping with observations made by other investigators studying head and neck patients.[18,19] We acknowledge that there may exist a subgroup of head and neck patients who may benefit from more prolonged administration of perioperative antibiotic prophylaxis. Further evaluation of patients undergoing skull base surgery, the use of free flaps, and mandibular reconstruction must be undertaken before this issue can be more precisely addressed.

In each of these studies, the antibiotic was administered intravenously 1 hour prior to surgery in keeping with the tenets established by Burke.[1] Failure to administer the antibiotic prior to contamination may render prophylaxis ineffective.

In summary, these comprehensive studies provide a rational basis for selection of antibiotics to be used as prophylaxis for contaminated oncologic head and neck surgery. Other factors including relative costs and potential side effects of these agents can be taken into consideration and would vary with the patient population, hospital situation, and experience of the surgeon.

Tissue Plasminogen Activator in Thrombolytic Therapy. 264 pp. Burton E. Sobel, Désiré Collen, Elliott B. Grossbard. New York: Marcel Dekker, Inc. 1987. $55.00.

One of the most remarkable of recent achievements in medicine has been the development of *tissue plasminogen activator* and its application as a thrombolytic agent in the management of a variety of thrombotic disorders. The editors of this authoritative monograph have summarized the current data concerning this impressive activator and presented it in a logical, thoughtful, and effective manner. The clinical use of *recombinant* tissue plasminogen activator (rt-PA) was initiated with the treatment of the first patient in February 1984, and in this text the data concerning management of more than 3000 patients treated in the United States, Europe, Australia, Canada, New Zealand, and Japan are summarized. The text proceeds through a review of pharmacokinetics, biological activity, and clinical pharmacology of tissue plasminogen activator with special attention to rt-PA.

In 1980, Rijken first produced 1 mg of t-PA from 5 kg of human uterine tissue using a special procedure. Working with Collen, Rijken later utilized a modification of this process to purify gram quantities of t-PA from a melanoma cell line. Although these techniques were tedious with a relatively low yield, nevertheless, a sufficient amount of highly purified t-PA was produced for extensive biological, physiological, and biochemical study. In 1981, Weimar and Collen reported two patients with renal vein thrombosis treated successfully with t-PA, and this report stimulated scientists at Genentech to successfully clone and express the human t-PA gene in Chinese hamster ovarian cells in tissue culture, the gene product called recombinant human tissue type plasminogen activator or rt-PA. In 1983, seven patients with acute myocardial infarction were treated with melanoma-derived t-PA, and six exhibited coronary thrombolysis. This prompted the formulation of a protocol for the multicenter trial of t-PA in the treatment of acute myocardial infarction with participation of investigators at Johns Hopkins, the Massachusetts General Hospital, and Washington University together with Genentech scientists. In 1984, the National Heart, Lung and Blood Institute (NHLBI) began a pilot trial with rt-PA, and the results confirmed those found by the earlier Genentech-sponsored protocol. Although a randomized double-blind trial comparing rt-PA with streptokinase was initiated by the NHLBI, it was not completed due to the fact that it became obvious that rt-PA was superior.

This is a very valuable monograph for all involved in the management of clinical conditions requiring fibrinolytic therapy. It is remarkable how rapidly rt-PA was developed and how successful it has been applied clinically. This text is essential for all those involved in investigative and clinical aspects of those disorders leading to intravascular thrombosis and its sequelae.

David C. Sabiston, Jr., M.D.
James B. Duke Professor of Surgery and Chairman of the Department
Duke University Medical Center
Durham, North Carolina

Essentials of Surgery. 1272 pp. David C. Sabiston, Jr. Philadelphia: W. B. Saunders Co. 1987. $39.95.

As Dr. Sabiston stated in his Preface, this textbook was initiated to meet a "need for a more compact text" for medical students based on the established standards of the highly successful *Textbook of Surgery: The Biological Basis for Modern Surgical Practice.* Although this textbook is about half the size of the standard text, it is fairly comprehensive, including surgical specialties such as cardiothoracic surgery, neurosurgery, plastic and maxillofacial surgery, orthopedics, otolaryngology, gynecology, urology, and pediatric surgery.

The first chapter in the book, appropriately entitled "Milestones in Surgery," succinctly chronicles the major historical developments in surgery. In addition, the historical development of the subject is briefly described in each section. This refreshing presentation of historical developments in surgery, particularly for medical students, is a reflection of Dr. Sabiston's scholarly interests.

Throughout the text, basic principles and fundamental concepts are emphasized but are elaborated on in chapters dealing with homeostasis and shock, fluid and electrolyte management, nutrition and metabolism in surgical patients, wound healing and management, surgical infections and choice of antibiotics, and anesthesia. A chapter is devoted to appropriate surgical consideration of virtually every organ in the body. Each chapter includes selected references with a short description of the contents. Appropriate illustrations of technical procedures, as well as tables, graphs, and algorithms, are generously sprinkled throughout the text to enhance the clarification of some of the more complex problems. At the end of the book is a most useful chapter on Normal Values, which is concerned with normal or reference values for the most commonly performed laboratory tests both in conventional units and in S.I. units (International System of Units).

In a thorough review of this textbook, I observed only one departure from a comprehensive, although often succinct, consideration of surgical problems, and that was in the section on Arterial Aneurysms in the chapter on The Arterial System. The only reference to aneurysms of the thoracic aorta is a statement that they may occur and that cystic medial necrosis is a common predisposing factor to dissecting aneurysms. Similarly, only a passing reference is made to dissection in the chapter on Acquired Diseases of the Aortic Valve. Yet, aneurysm of the abdominal aorta is adequately discussed in the chapter on The Arterial System. It is almost captious to make this comment since obviously some judgments had to be made in condensing the text.

Although this textbook is directed primarily toward providing "information expected to be acquired by medical students prior to graduation," in the opinion of this reviewer, it is highly recommended for residents training in surgery and even for practicing surgeons. It provides an excellent and authoritative quick reference to virtually all conditions requiring surgical consideration.

As might be expected from the author who is recognized not only for his investigative and clinical capabilities but also for his scholarly and literary qualities, the textbook material is highly readable, despite a number of different contributors.

MICHAEL E. DEBAKEY, M.D.
Houston, Texas

Current Therapy in Critical Care Medicine. 355 pp. Joseph E. Parrillo. Philadelphia: B. C. Decker, Inc. 1987. $49.00.

WITH THE RECOGNITION OF the increasing complexity of and the unique body of knowledge associated with intensive care, there has been a proliferation of textbooks and monographs dealing with various aspects of critical illness. Some have focused on specific topics, such as cardiopulmonary pathophysiology and support, whereas others have attempted to deal with the full panoply of issues confronting those who care for critically ill patients. This volume is of the latter category. It is intended to provide the "active . . . critical care physician" with current therapeutic information. Like most similar texts, it is multiauthored, and, as with so many other texts, that multiauthorship is both a strength and a weakness.

The format of the book is reasonable, although it is not clear why such topics as tracheal intubation, bronchoscopy, and mechanical ventilation were included in the section on Diagnostic and Therapeutic Techniques rather than the Pulmonary section. A more serious problem with the format is that the editor has chosen to omit bibliographic references, even for areas that are highly controversial (Ethical Issues) or very technical but briefly summarized (Burns and Electical Injuries). The result of this omission is that the reader who wishes to increase the depth of his knowledge on a particular subject is forced to turn to a different text for source material.

Although there is excellent treatment by internationally recognized experts of some topics (Bedside Hemodynamic Monitoring, Interstitial Lung Disease), other topics are less well covered. Moreover, there is a lack of consistency between the treatment of specific issues given in different chapters. For example, in a discussion of weaning from mechanical ventilation, one chapter advocates T-piece trials, whereas another does not. Elsewhere, one author advocates the use of colloid for volume resuscitation; in a different chapter discussing the same subject, crystalloid therapy is advised. There is no attempt by the editor to reconcile these differences.

This book has a reasonable idea as its premise. It is unfortunate that it frequently leaves the reader with many unanswered questions.

C. JAMES CARRICO, M.D.
Seattle, Washington

Surgical Management of Morbid Obesity, Vol. 12 in the series **Science and Practice of Surgery.** 320 pp. Ward O. Griffen, Jr., Kenneth J. Printen. New York: Marcel Dekker, Inc. 1987. $79.75.

A RECENT VISITING PROFESSOR from China, when asked about his most significant impression about the United States, replied readily that he was most struck by the large number of fat Americans. His observation is readily confirmed by a visit to any shopping mall; morbid obesity has become a common and almost epidemic disorder. The enormous excess of weight is a clear health hazard; the disease is associated with a high incidence of diabetes mellitus, hypertension, vascular disease, biliary disease, arthritis, malnutrition, and sharp limitations of functional effectiveness.

The small book, *Surgical Management of Morbid Obesity,* presents an excellent and concise summary of our current approaches to this serious disease. The book was written by some of the pioneers who recognized years ago that morbid obesity is an illness serious enough to warrant surgery and who then went on to design and test a broad variety of operations. The development of the current procedures has not come easily; an interesting facet of the book is its excellent presentation of the history of bariatric surgery.

Under the obviously excellent editorial control of Griffen and Printen, such well-known obesity surgeons as Mason, Halverson, and Scopinaro present not only their approaches in detail, but also report a treasure of data from their experience and share useful hints about patient management. With the exception of Scopinaro's contribution, which is a bit long, the remainder of the chapters are unusually concise, well organized, and informative.

The book is not only an essential reference for anyone involved in bariatric surgery, it is also a textbook of gastric physiology. Doctors Griffen and Printen deserve our thanks and our congratulations for this important contribution to the surgery of morbid obesity.

WALTER J. PORIES, M.D.
Greenville, North Carolina

Atlas of Clinical Gastroenterology. 283 pp. J. J. Misiewicz, C. I. Bartram, P. B. Cotton, A. S. Mee, A. B. Price, R. P. H. Thompson. Philadelphia: Lea & Febiger. 1987. $110.00.

THIS BOOK, *Atlas of Clinical Gastroenterology,* which arrived on my desk for review a week or so ago, is no ordinary atlas by any stretch of the imagination. Rather, it is an informative, comprehensive comparison of normal and diseased structures as depicted by beautiful photographs of gross microscopic and ultramicroscopic anatomy displayed in luxuriant colors and by conventional x-rays and scans. Anatomic diagrams help the readers' understanding of the figures. The first part of each section is an identifiable introduction to the normal organ structure, innervation, and function leading to an illuminating display of gastrointestinal and hepatobiliary pathology. It is so clearly well done that comparison easily becomes contrast.

For each organ, the authors have described all important diseases and have included lesser ones, which lend themselves to beautiful illustrations (*e.g.*, abetalipoproteinemia, intestinal lymphangiectasia). Especially helpful in this organ recital are the diagrams that accompany practically all of the illustrations of gross pathology, x-rays, scans, etc.

The text is brief (as it should be for the purposes of such a volume), clear, and to the point. Collectively, it encompasses a lot of information. A special value of the work, of course, is that it comprehensively correlates findings of the most up-to-date techniques for diagnosis with the beautiful illustrations of gastrointestinal pathology as demonstrated by new scanning techniques, endoscopy, histochemistry, and ultramicroscopy. Slides of all this material undoubtedly comprise the best teaching collection of gut and liver pathology extant.

Especially valuable are the pictorial and descriptive evolutions of some of the more important diseases. Thus we see the progressive changes from benign colon adenoma to invasive cancer, from diverticula to diverticulitis, and from uncomplicated duodenal ulcer to bleeding or perforation. The endoscopic illustrations will especially delight teachers and the students of gastroenterology studying the gross differences between benign and malignant tumors, between various forms of vascular anomalies, and between ischemic and inflammatory ulceration and necrosis.

We are indebted to Dr. J. J. Misewicz and his authoritative colleagues who have given us the best illustrations and descriptive summaries of normal gut and liver anatomy and physiology, and of their clinically important diseases. Their demonstration of the contributions of modern techniques to diagnosis of disease and to understanding correlations of normal structure and function and of disease and dysfunction, will serve as an effective introduction to gastroenterology. The *Atlas of Clinical Gastroenterology* is a major effort and it will be a work to which we all will refer again and again.

MARVIN H. SLEISENGER, M.D.
San Francisco, California

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

Title page
Abstract and key words
Text
Acknowledgments
References
Tables: each table, complete with title and footnotes, on a separate page
Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

Methods: Describe your selection of the observational or experimental subjects (patients or experimental animals, including controls) clearly. Identify the methods, apparatus (manufacturer's name and address in parentheses), and procedures in sufficient detail to allow other workers to reproduce the results. Give references to established methods, including statistical methods; provide references and brief descriptions of methods that have been published but are not well known; describe new or substantially modified methods, give reasons for using them, and evaluate their limitations.

When reporting experiments on human subjects, indicate whether the procedures followed were in accord with the ethical standards of the Committee on Human Experimentation of the institution in which the experiments were done or in accord with the Helsinki Declaration of 1975. When reporting experiments on animal subjects, indicate whether the institution's or the National Research Council's guide for the care and use of laboratory animals was followed. Identify precisely all drugs and chemicals used, including generic name(s), dosage(s), and route(s) of administration. Do not use patients' names, initials, or hospital numbers.

Include numbers of observations and the statistical significance of the findings when appropriate. Detailed statistical analyses, mathematical derivations, and the like may sometimes be suitably presented in the form of one or more appendixes.

Results: Present your results in logical sequence in the text, tables, and illustrations. Do not repeat in the text all the data in the tables and/or illustrations: emphasize or summarize only important observations.

Discussion: Emphasize the new and important aspects of the study and *conclusions* that follow from them. Do not repeat in detail data given in the Results section. Include in the Discussion the implications of the findings and their limitations and relate the observations to other relevant studies. Link the conclusions with the goals of the study but avoid unqualified statements and conclusions not completely supported by your data. Avoid claiming priority and alluding to work that has not been completed. State new hypotheses when warranted, but clearly label them as such. Recommendations, when appropriate, may be included.

ACKNOWLEDGMENTS

Acknowledge only persons who have made substantive contributions to the study. Authors are responsible for obtaining written permission from everyone acknowledged by name because readers may infer their endorsement of the data and conclusions.

REFERENCES

Number references consecutively in the order in which they are first mentioned in the text. Identify references in text, tables, and legends by arabic numerals (in parenthesis). References cited *only* in tables or in legends to figures should be numbered in accordance with a sequence established by the first identification in the text of the particular table or illustration.

Use the form of references adopted by the U.S. National Library of Medicine and used in *Index Medicus*. Use the style of the examples cited at the end of this section, which have been approved by the National Library of Medicine.

The titles of journals should be abbreviated according to the style used in *Index Medicus*. A list of abbreviated names of frequently cited journals is given near the end of this document; for others, consult the "List of Journals Indexed," printed annually in the January issue of *Index Medicus*.

Try to avoid using abstracts as references; "unpublished observations" and "personal communications" may not be used as references, although references to written, not verbal, communications may be inserted (in parentheses) in the text. Include among the references manuscripts accepted but not yet published; designate the journal followed by "in press" (in parentheses). Information from manuscripts submitted but not yet accepted should be cited in the text as "unpublished observations" (in parentheses).

The references must be verified by the author(s) against the original documents.

Examples of correct forms of references are given below.

Journal

1. Standard Journal Article (List all authors when six or less; when seven or more, list only first three and add et al.)

9. Magazine Article

   Roueché B. Annals of medicine: the Santa Claus culture. The New Yorker 1971 Sep 4:66–81.

TABLES

Type each table on a separate sheet: remember to double space. Do not submit tables as photographs. Number tables consecutively and supply a brief title for each. Give each column a short or abbreviated heading. Place explanatory matter in footnotes, not in the heading. Explain in footnotes all nonstandard abbreviations that are used in each table. For footnotes, use the following symbols in this sequence: *, †, ‡, §, ||, ¶, **, ††. . . . Identify statistical measures of variations such as SD and SEM.

Omit internal horizontal and vertical rules.

Cite each table in the text in consecutive order.

If you use data from another published or unpublished source, obtain permission and acknowledge fully.

Having too many tables in relation to the length of the text may produce difficulties in the layout of pages. Examine issues of the journal to which you plan to submit your manuscript to estimate how many tables to use per 1000 words of text.

The editor on accepting a manuscript may recommend that additional tables containing important backup data too extensive to be published may be deposited with the National Auxiliary Publications Service or made available by the author(s). In that event, an appropriate statement will be added to the text. Submit such tables for consideration with the manuscript.

ILLUSTRATIONS

Black-and-white illustrations and tabular material will be published free in moderate numbers. Excess illustrations, excess tabular material, and all color illustrations will be charged to the author. Submit the required number of complete sets of figures. Figures should be professionally drawn and photographed; freehand or typewritten lettering is unacceptable. Instead of *original* drawings, roentgenograms, and other material, send sharp, glossy black-and-white photographic prints, usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.). Letters, numbers, and symbols should be clear and even throughout, and of sufficient size that when reduced for publication each item will still be legible. Titles and detailed explanations belong in the legends for illustrations, not on the illustrations themselves.

Each figure should have a label pasted on its back indicating the number of the figure, the names of the authors, and the top of the figure. Do not write on the back of the figures or mount them on cardboard, or scratch or mar them using paper clips. Do not bend figures.

Photomicrographs must have internal scale markers. Symbols, arrows, or letters used in the photomicrographs should contrast with the background.

If photographs of persons are used, either the subjects must not be identifiable or their pictures must be accompanied by written permission to use the photograph.

Cite each figure in the text in consecutive order. If a figure has been published, acknowledge the original source and submit written permission from the copyright holder to reproduce the material. Permission is required, *regardless of authorship or publisher*, except for documents in the public domain.

For illustrations in color, supply color negatives or positive transparencies and, when necessary, accompanying drawings marked to indicate the region to be reproduced; in addition, send two positive color prints to assist editors in making recommendations.

LEGENDS FOR ILLUSTRATIONS

Type legends for illustrations double spaced, starting on a separate page with arabic numerals corresponding to the illustrations. When symbols, arrows, numbers, or letters are used to identify parts of the illustrations, identify and explain each one clearly in the legend. Explain internal scale and identify method of staining in photomicrographs.

ABBREVIATIONS

Use only standard abbreviations (*see* below for lists of commonly used approved abbreviations). Consult the following sources for additional standard abbreviations: [1] CBE Style Manual Committee. Council of Biology Editors style manual: a guide for authors, editors, and publishers in the biological sciences. 4th ed. Arlington: Council of Biology Editors, 1978; and [2] O'Connor M, Woodford FP. Writing scientific papers in English: an ELSE-Ciba Foundation guide for authors. Amsterdam, Oxford, New York: Elsevier-Excerpta Medica, 1975. Avoid abbreviations in the title. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

In most countries the International System of Units (SI) is standard or is becoming so. Report measurements in the units in which they were made. Journals may use these units, convert them to another system, or use both.

COMMONLY USED APPROVED ABBREVIATIONS

Standard Units of Measurement

Term	Abbreviation or Symbol
ampere	A

SUBMISSION OF MANUSCRIPTS

Mail the required number of manuscript copies in a heavy paper envelope, enclosing the manuscript copies and figures in cardboard, if necessary, to prevent bending of photographs during mail handling. Place photographs and transparencies in a separate heavy paper envelope.

Manuscripts should be accompanied by a covering letter from the author who will be responsible for correspondence regarding the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors. The letter should give any additional information that may be helpful to the editor, such as the type of article the manuscript represents in the particular journal, information on publication of any part of the manuscript, and whether the author(s) will be willing to meet the cost of reproducing color illustrations. Include copies of any permissions needed to reproduce published material or to use illustrations of identifiable subjects.

PUBLISHER'S NOTICES

CHANGE OF ADDRESS: Please allow 60 days before date of issue for change of address. Notification should include the old as well as the new address, with indication of whether the change is temporary or permanent. Please give the name of the journal.

Change of Address and Subscription correspondence for all countries except Japan should be sent to:

ANNALS OF SURGERY
Journal Fulfillment Department
Lippincott/Harper
2350 Virginia Avenue
Hagerstown, MD 21740

Correspondence about subscriptions in Japan should be sent to:

Woodbell Scope Incorporated
Mansui Building
9-18, Kanda Surugadai 2-chome
Chiyoda-ku
Tokyo 101, Japan

Copies will not be replaced without charge unless we receive a request within 60 days of the mailing in the U.S. or within 5 months in all other countries.

BUSINESS ADDRESS: Reprints, advertising, and all business communications should be addressed to:

ANNALS OF SURGERY
J. B. Lippincott Company
East Washington Square
Philadelphia, PA 19105

CLASSIFIED AD SECTION

Classified advertising is available in **ANNALS OF SURGERY** for those recruiting personnel or interested in obtaining positions. Display space also is available for those desiring greater visibility or more space for their message.

Classified ad copy, like other advertising copy, will be reviewed for approval prior to publication.

Classified Rates: $9.00 per line or fraction of line. The average line will be 40 characters.

Box Numbers: Replies may be directed via Box # to J.B. Lippincott Company, at an extra charge per insertion of $6.50 to cover handling costs in forwarding such replies to the advertiser.

How to Order: Send typewritten text copy for the ad with remittance in full to:

ANNALS OF SURGERY
c/o J.B. Lippincott Company
Attn: Janet Eagan
East Washington Square
Philadelphia, Pa. 19105
(215) 238-4215

Deadline: Copy received by the 15th of month will run in the second following month's issue, e.g. November 15th for January issue. Ads received after the 15th will run in the next available issue.

BOARD CERTIFIED OR ELIGIBLE GENERAL SURGEON—The VA Medical Center in Jackson, Mississippi, a 455 bed facility, affiliated with the University of Mississippi School of Medicine is recruiting for a General Surgeon with peripheral vascular capabilities. As a major teaching affiliate, the position will necessitate an active interest in teaching medical students and residents. The candidate will be eligible for an academic appointment at the University. To apply, send your CV to: **Dr. T. K. Williams, Acting Chief, Surgical Service (112), VA Medical Center, 1500 E. Woodrow Wilson Drive, Jackson, MS 39216.**

BOULDER, COLORADO: Thirty-five physician multispecialty group seeking Board Eligible/Board Certified General Surgeon with interest in Thoracic/Vascular surgery. Interested please send CV to **John Day, M.D., Boulder Medical Center, P.C., 2750 Broadway, Boulder, CO 80302.**

Chief, Surgical Service—Veterans Administration Medical Center, Albuquerque, NM and University of New Mexico School of Medicine are seeking an individual to lead active clinical, teaching and research programs for undergraduates and residents in General, Thoracic, Plastic, Urologic and Orthopaedic Surgery. Individual will have major clinical and academic responsibilities and must have experience and accomplishments to qualify for senior academic appointment in the Department of Surgery, University of New Mexico, School of Medicine. Inquiries should be accompanied by resume and addressed to **Donald E. Fry, M.D., Chairman, Dept. of Surgery, c/o Chief of Staff, VA Medical Center, 2100 Ridgecrest Drive S.E., Albuquerque, New Mexico 87108. VA Medical Center, Albuquerque is an equal opportunity employer.**

ALL SURGICAL SPECIALTIES, NATIONWIDE. Excellent quality of life and compensation. **Dr. Len Goodman, SMA, P.O. Box 25786, Charlotte, NC 28229. 704-536-2527.**

BC/BE General Surgeon to associate with two active internists in NE Wisconsin. New clinic and modern hospital with state of the art ICU. **ANN1B, J.B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

GEN SURG-BC/BE, Univ. trained, to join busy 3 man group Sub. Phila. Active res. teaching affil. with Hahnemann Univ. Graduated annual salary plus expenses and benefits leading to partnership. Training or expertise in vascular surgery preferred. **Box ANN1C, J.B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

GENERAL SURGEON—Board Certified or Board Eligible general surgeon to join two young general surgeons in Palmer, Alaska. The position is with a busy, well established rural practice in a four year old hospital and three year old office building, forty miles from Anchorage. Unparalleled outdoor activities. Send resume to **Michael R. Senta, M.D., 561 S. Denali, Suite D, Palmer, Alaska 99645.**

General Surgeon—Two general surgeons searching for BC/BE American trained M.D. to join busy practice covering three small rural central Washington hospitals. Located in orchard/vineyard country with dry pleasant climate, near skiing, hunting and fishing. Excellent fringe benefits, $80,000 first year salary. Send CV to **Box ANN1A, J.B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

GENERAL SURGEONS—Newly established prepaid group practice desires to begin offering general surgery services. Looking for general surgeons interested in establishing and building a department. Physicians must be from high quality residency programs. Positions available immediately. CVs to: **Larry A. Oates, M.D., Regional Medical Director, Carolina Permanente Medical Group, P.A., 2900 Highwoods Blvd., Raleigh, N.C. 27604, (919) 878-9870.**

MAINE: Opportunity for BC/BE general surgeon to join established two-man surgical group in northern Maine. Subspecialty training helpful but not required. Progressive family-oriented university community. Affiliated with well-qualified, 40-member primary care and subspecialty medical staff and modern multi-facility hospital. Competitive salary plus benefits leading to future partnership. For further information, please forward curriculum vitae to **John Ginty, Associate Director, The Aroostook Medical Center, P.O. Box 151, Academy Street, Presque Isle, ME 04769.**

SOUTHEASTERN NEW MEXICO: We are seeking a board certified/board eligible general surgeon interested in a lucrative career move with a first year guaranteed salary of $90,000+. This up-to-date private practice has a service area population of approximately 30,000. For additional information, please send current CV to **Linda Smith, Central Business Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri, 64111; or call 1-800-821-5147 or 816-561-1025.**

KANSAS: We are seeking a general surgeon interested in a full-time private practice opportunity in the greater Kansas City area. For further information, please send current CV to **Linda Smith, Central Business Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri, 64111; or call 1-800-821-5147 or 816-561-1025.**

The Department of Surgery of the University of South Dakota is seeking full time academic surgeons. An excellent research facility and opportunities for private practice are available. Salary and benefits are highly competitive. Closing date for receipt of applications is March 1, 1988 or until position is filled. Please forward curriculum vitae to **Frank E. Jones, M.D., Chairman, Search Committee, 2501 West 22nd Street, Sioux Falls, SD 57105.** The University of South Dakota is an equal employment opportunity/affirmative action employer.

The Department of Surgery, Stanford University School of Medicine, is searching for an individual to assume a full-time faculty position at the University Hospital in General Surgery. We are recruiting for a general surgeon with a special interest in gastrointestinal or vascular surgery. The appointment is expected to be at the Assistant Professor level. Appropriate levels of academic achievement and promise, clinical skill, and teaching ability are prerequisites. Letters of inquiry and curricula vitae should be sent to **Harry A. Oberhelman, Jr., M.D., Division of General Surgery, S067, Stanford University Medical Center, Stanford, California 94305.** Stanford is an equal opportunity employer and welcomes nominations of women and minority group members and applications from them.

TRAUMA DIRECTOR—A 407-bed acute care hospital in southeastern U.S. seeks a Trauma Director for its Trauma Service. Teaching hospital with surgical residents. Attractive community that ranks high on "best places to live". Be responsible for all components of Trauma Service including direction of Level II Trauma Center and possibly Level I. Minimum guarantee to become established. Candidates must be Board Certified in General or Thoracic Surgery, with training and experience in Trauma Surgery. Send curriculum vitae and references to: **D. Gene Clark, Administrator and CEO, Johnson City Medical Center Hospital, 400 State of Franklin Road, Johnson City, Tennessee 37604-6094.**

This Publication is available in Microform.

5th Annual International
Breast Cancer Seminar

Presented in Cooperation with the American Cancer Society

MIAMI

March 24 - 26, 1988

HOTEL INTER•CONTINENTAL MIAMI

Join 14 leading specialists from all over the world at this post graduate seminar. They will be discussing the latest developments in the diagnosis and treatment of all forms of breast disease.

Participants Include:

JOHN BOSTWICK, III, M.D.
Emory Clinic, Section of Plastic and Reconstructive Surgery, Atlanta, Georgia

DIANA BRINKLEY, M.D.
Consultant in Radiotherapy and Oncology, London

AMAN U. BUZDAR, M.D.
Professor of Medicine, Medical Breast Service, University of Texas, M.D. Anderson Hospital, Houston, Texas

ROBERT CALLAHAN, Ph.D.
Chief, Oncogenetics Section, Laboratory of Tumor Immunology and Biology, National Cancer Institute

GARY M. CLARK, M.D.
University of Texas, Health and Science Center, Department of Medicine/Oncology, San Antonio, Texas

ISAIAH J. FIDLER, D.V.M., Ph.D.
Professor and Chairman, Department of Cell Biology, M.D. Anderson Hospital and Tumor Institute, Houston, Texas

BERNARD FISHER, M.D.
Distinguished Service Professor, Department of Surgery, University of Pittsburgh, School of Medicine

ROBERT L. GOODMAN, M.D.
Professor and Chairman, Department of Radiation Therapy, University of Pennsylvania School of Medicine

FRANK E. GUMP, M.D.
Chief, Breast Service, Columbia-Presbyterian Medical Center, New York

DANIEL KOPANS, M.D.
Director of Breast Imaging, Harvard Medical School

LANCE LIOTTA, M.D.
Pathology Department, National Cancer Institute

SUSAN M. LOVE, M.D.
Director of Breast Clinic, Beth Israel Hospital, Boston

BERNARD PIERQUIN, M.D.
Chief, Dept. Cancerologie, Henri Mondor Hospital, France

LASZLO TABAR, M.D.
Mammography Dept., Central Hospital, Falun, Sweden

Approved for 17 hours of Category I Credit.

For more information on the 5th Annual International Breast Cancer Seminar, mail to: MIAMI CANCER CONFERENCE, INC.
P.O. Box 4593, Hialeah, FL 33014-0593

PHYSICIANS

TRAUMA SURGEONS

Two excellent opportunities to join thriving private practices in Allentown, Pennsylvania.

A trauma surgeon is being sought by a six-man group to participate in the group's trauma and general surgical case load with emphasis on surgical critical care and resident teaching.

A trauma surgeon is needed to become a second member of a hospital trauma practice to participate in the trauma case load, surgical critical care, teaching and to assist in administration of the trauma program.

Both positions would practice primarily at the Lehigh Valley Hospital Center, Pennsylvania's first Level I designated Trauma Center. Over 1800 trauma patients are seen by the Trauma Center including 600 patients with an ISS greater than 15. The Trauma Center includes a 12-bed dedicated shock/trauma unit, an 8-bed central nervous system unit, a 6-bed burn center and a special resuscitation area including a 24-hour fully equipped trauma operating room. The Trauma Center is supported by a six year old on-site helicopter program. The Trauma service supports a trauma fellow and five shock/trauma residents dedicated only to the trauma service. The trauma/general surgeon will also have a significant practice at The Allentown Hospital, with regional infant, children, women's, renal and psychiatric services.

Qualified candidates must be board eligible or certified in general surgery and eligible/certified in surgical critical care. Training and experience in the care of trauma and critical care patients a must. Interested applicants send resumes to:

Vital Information For Your Surgical Practice!

New! **New!**

PHYSIOLOGIC BASIS OF MODERN SURGICAL CARE

Edited by Thomas A. Miller, M.D., F.A.C.S., and Contributing Editor Brian J. Rowlands, M.D., F.R.C.S., F.A.C.S.; with 100 contributors.

Providing a timely and up-to-date review, this reference approaches surgical disorders as derangements in normal physiology. The most comprehensive text available, it will enhance your diagnostic skills and allow you to provide optimal patient care.

- Up-to-date physiology with clinical applications
- Explains diagnostic signs and symptoms in terms of physiologic dysfunction and correlates these symptoms with the use of laboratory and imaging studies
- Sequences order in which tests should be used
- Emphasizes clinical applications while also providing a thorough explanation of normal physiology

February, 1988. Approx. 1,072 pages, 616 illustrations. (03421) About $75.00 (U.S.); $103.50 (Can.)

CLINICAL SURGERY

Edited by John H. Davis, M.D.; William R. Drucker, M.D.; Rodger S. Foster, Jr., M.D.; Richard L. Gamelli, M.D.; Donald S. Gann, M.D.; Basil A. Pruitt, Jr., M.D.; and George F. Sheldon, M.D.; with 105 contributors.

Taking you a step further than other comprehensive surgical references, CLINICAL SURGERY explores the future of surgery. The unique problem-solving, symptom-oriented approach allows easy access to information for daily use and facilitates the study of surgery — providing the best method of review for board examinations.

- convenient summary charts after each organ systems chapter feature differential diagnosis and treatment recommendations
- decision-making algorithms guide you to the correct diagnosis and best treatment alternative

1987. 3,530 pages, in two volumes, 1,539 illustrations and 41 color plates. (01213) $120.00 (U.S.); $165.75 (Can.)

MSA-012-017

New!

PRINCIPLES OF BASIC SURGICAL PRACTICE

Edited by Edwin C. James, M.D.; Robert J. Corry, M.D.; and John F. Perry, Jr., M.D., PhD.; with 79 contributors.

Superbly illustrated and up-to-date, this synoptic reference is for those who have little time to wade through the big "universe of surgery" texts.

- covers anatomic and physiologic relationships, along with diagnostic and management considerations common to everyday surgical practice

1987. 598 pages, illustrated. A Hanley & Belfus, Inc. publication. (02368) $41.00 (U.S.); $56.75 (Can.)

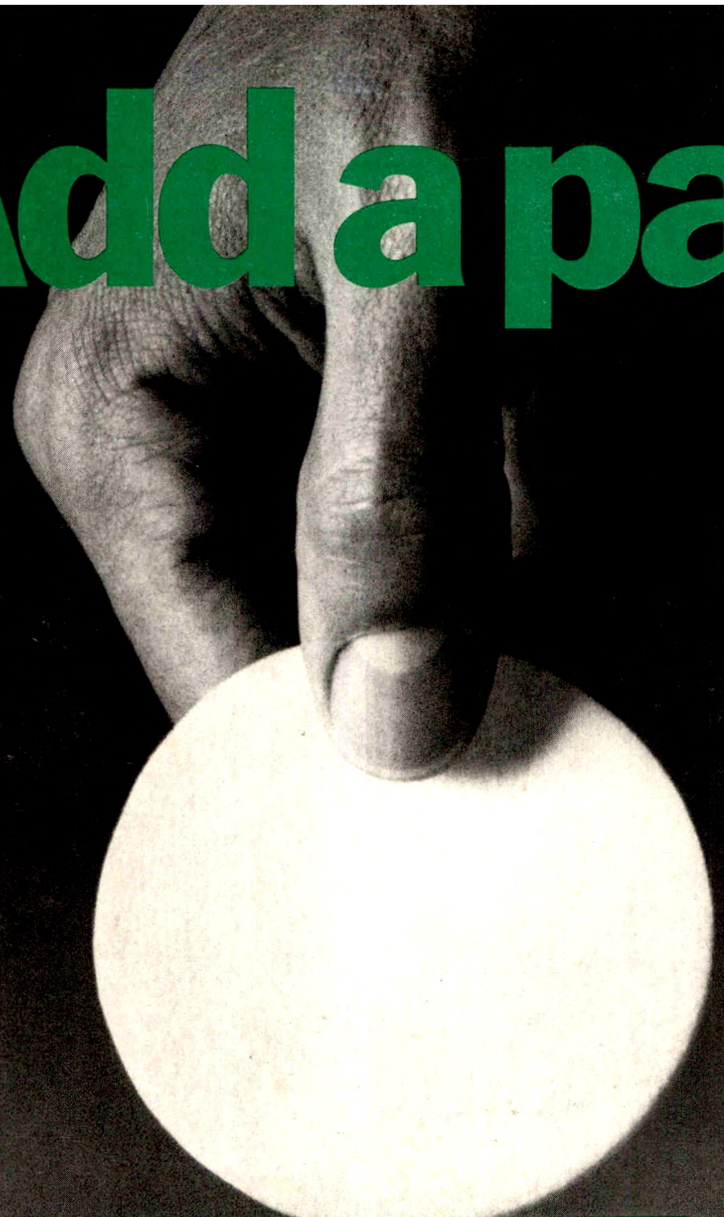
Add a pad.



TUCKS®

Pre-Moistened Hemorrhoidal/Vaginal Pads

To change the course of anorectal therapy

Added to any anorectal regimen, TUCKS pads provide complementary benefits no single anorectal preparation alone can offer. TUCKS pads act instantly, on contact, to soothe, cool, and comfort tender, irritated anorectal tissue. And TUCKS cleanses as it soothes to gently remove potentially irritating fecal residue.

So the next time you're recommending an anorectal ointment, cream, or suppository, recommend the addition of TUCKS. It adds up to more effective anorectal therapy.

CEFOTAN® IM/IV
(cefotetan disodium)

Please see adjacent page
for brief summary
of prescribing information.

STUART PHARMACEUTICALS
Division of ICI Americas Inc
Wilmington, Delaware 19897

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

Title page
Abstract and key words
Text
Acknowledgments
References
Tables: each table, complete with title and footnotes, on a separate page
Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

Recurrent Hepatic Hemangiomas

Possible Association with Estrogen Therapy

ROBERT L. CONTER, M.D. and WILLIAM P. LONGMIRE, JR., M.D., F.A.C.S.

Hemangiomas are the most common benign tumors occurring in the liver. However, the natural history of hepatic hemangiomas has not been well defined. Four patients (3 women, 1 man) with recurrent giant liver hemangiomas underwent either surgical or radiation therapy as initial treatment for the primary tumor. The average time until recurrence was 14 years, and each tumor weighed more than 600 g. Each of the female patients had been given chronic estrogen (Premarin) replacement therapy. Three of the four patients underwent surgical resection for intractable symptoms or progressive enlargement. It is believed that estrogen replacement therapy may play a role in the pathogenesis of these tumors. Furthermore, operative intervention should be considered in patients with recurrent giant liver hemangioma.

HEMANGIOMAS ARE THE MOST COMMON benign tumors occurring in the liver.[1] Small hemangiomas of the liver are generally asymptomatic. However, giant hemangiomas, those larger than 4 cm, frequently present as an abdominal mass associated with vague symptoms of upper abdominal pain and fullness. Since a risk of fatal spontaneous hemorrhage from these hemangiomas exists,[2] the majority of surgeons believe that symptomatic giant hemangiomas of the liver require surgical intervention.

From the Department of Surgery, UCLA Hospital and Clinics, Los Angeles, California

The natural history of hepatic hemangioma has not been well defined. Factors that allow some lesions to remain dormant or regress and others to undergo rapid growth are poorly understood. Four patients who had previously received either surgical or radiation therapy for large symptomatic liver hemagiomas have recently been managed at UCLA. Each of these patients returned with similar clinical findings and were found to have recurrent hepatic hemangiomas. Their individual case reports follow and form the basis for this paper (Table 1).

Case Reports

Case 1

A 59-year-old woman presented with epigastric and right-sided abdominal pain and bloating. Thirteen years prior to her admission she was diagnosed as having a large hepatic hemangioma and underwent 5 months of cobalt radiation therapy. Follow-up liver-spleen scan showed that the liver mass had receded, and her symptoms disappeared. She returned 13 years later with upper abdominal symptoms, and subsequent angiogram revealed evidence of a recurrent hemangioma (Fig. 1). Her past history was remarkable considering her total hysterectomy at age 39 and Premarin hormone replacement for 20 years. She underwent a right hepatectomy for removal of a recurrent

TABLE 1. *Clinical Summary of Patients with Recurrent Giant Hemangiomas*

Patient No.	Initial Treatment	Time to Recurrence (yr)	Tumor Size (g)	Estrogen Therapy	Treatment of Recurrence
1	Radiation	13	950	Premarin	Surgery
2	Radiation	16	810	None	Surgery
3	Surgery	17	650	Premarin	Observation
4	Surgery	11	690	Premarin	Surgery

hemangioma weighing 950 g. In addition, a smaller hemangioma was removed from the left lateral segment. Pathologic diagnosis of both specimens revealed cavernous hemangioma. During the ensuing 8 years she has been well and without further abdominal symptoms or change in her liver scan.

Case 2

A 49-year-old male physician was diagnosed with a hemangioma involving the entire left lobe of the liver during laparotomy for cholecystitis. He was subsequently treated with postoperative radiation (dose unknown) and remained symptom-free for 16 years until he was admitted to UCLA with recurrent attacks of fever, chills, upper abdominal pain, and transitory jaundice. A firm 15-cm mass was palpable to the left of the xiphoid and a large filling defect was demonstrated in the left lobe of the liver. At laparotomy, following a negative common bile duct exploration, a left hepatic lobectomy removed an 810-g mass (Fig. 2). Pathologic diagnosis revealed multiple capillary and cavernous hemangiomas with areas of extensive scarring and necrosis. A bile duct was identified entering the tumor mass. It was assumed that pieces of necrotic tissue embolized into the biliary systems causing his intermittent attacks of fever and jaundice. He was well for 3 years following resection until he was found to have hemangiopericytoma in the left chest, unrelated to the hepatic hemangioma. This patient was also found to have a melanoma near the left scapula treated by excision and systemic chemotherapy (thiotepa) at age 48.

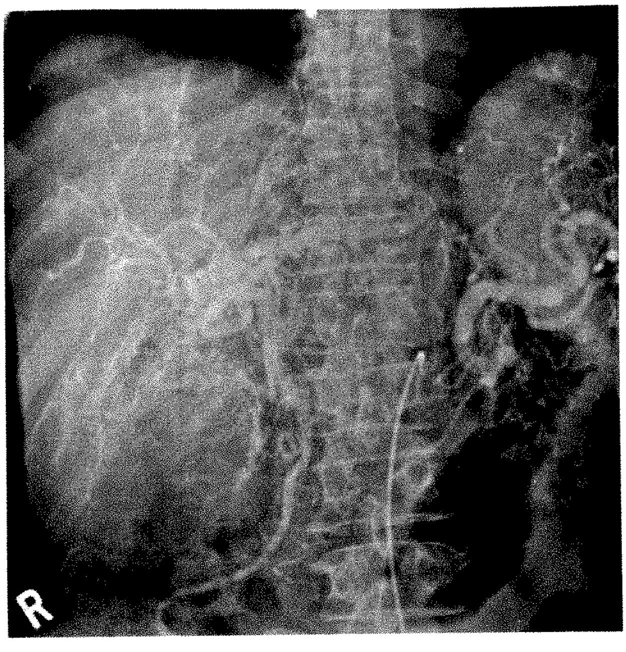

FIG. 1. Angiogram of a recurrent cavernous hemangioma; note downward and medial displacement of gastroduodenal artery from a giant hemangioma of the right lobe of the liver.

Case 3

A 57-year-old woman was referred to UCLA in 1969 after a laparotomy revealed a large cystic mass in the left lobe of the liver. She had presented with symptoms of abdominal pain, early satiety, weight loss, and a mass in the left upper quadrant. Her past history was remarkable considering that she had an appendectomy and total hysterectomy at age 37 with chronic estrogen replacement therapy. An arteriogram demonstrated a large mass in the lateral segment of the left lobe of the liver. A left lateral segmentectomy was performed for a 900-g cavernous hemangioma (Fig. 3). A few small punctate hemangiomas were seen in the medial segment of the left lobe. She has been asymptomatic for 17 years. However, during the course of a recent evaluation for an unrelated gynecologic condition, a CT scan revealed a 7-cm mass in the remaining left lobe consistent with cavernous hemangioma. She has stopped taking premarin and has been advised to have routine follow-up scans and observation. Surgery is considered unwarranted for this recurrent asymptomatic hemangioma in this 74-year-old patient.

Case 4

A 55-year-old woman presented to UCLA with complaints of an enlarging abdomen with right-sided abdominal pain, nausea, and vomiting. These symptoms had gradually increased in intensity over a period of 17 years finally becoming severe enough to cause the patient to seek medical attention. Evaluation revealed a large mass in the right lobe of the liver. A 650-g cavernous hemangioma was removed via an extended right hepatectomy; however, it was not possible to completely excise the lesion since it surrounded both right and left hepatic veins. She remained in good health for 11 years until similar symptoms recurred and she again sought relief. A hepatic angiogram demonstrated an extensive vascular lesion (Fig. 4). Understanding that it would be impossible to completely excise this lesion, the patient underwent a partial hepatic resection for a recurrent cavernous hemangioma (690 g). She remains asymptomatic without enlargement on CT scan 1 year following resection. It is interesting to note that this patient was taking Premarin for over 15 years, 5 years prior to her first hepatectomy.

Discussion

To the best of our knowledge, this paper represents the first report of recurrent hepatic hemangiomas following ablative treatment. Growth of the tumor was quite slow, and surgical resection was performed for intractable symptoms or progressive enlargement. Three of the four recurrences developed in patients receiving estrogen therapy. This pattern of recurrence may repre-

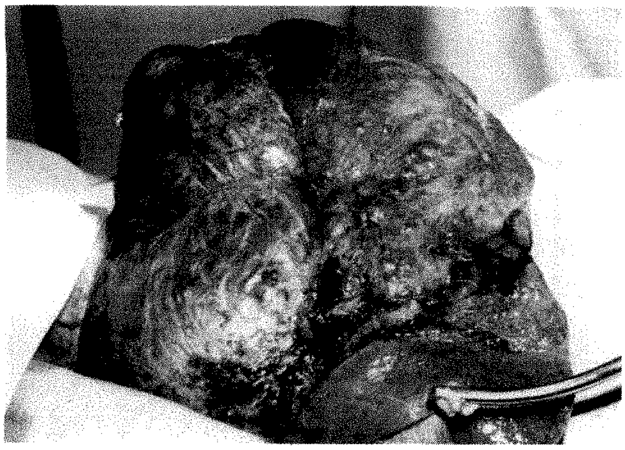

FIG. 2. Operative photograph of a recurrent giant hemangioma of the medial segment of the left lobe of the liver; the clamp points to the grossly normal left lateral segment.

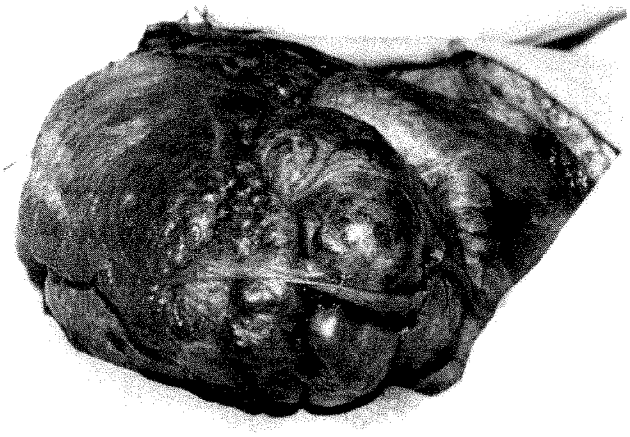

FIG. 3. Photograph taken at laparotomy for recurrent hemangioma of the lateral segment of the left lobe of the liver.

sent a new manifestation in the natural history of this disease.

Hemangiomas are the most common benign tumors of the liver. The first report of a liver hemangioma was by Frerichs[3] in 1861. Adami[4] described 20 cases (1.4%) of cavernous hemangioma in 1400 autopsies, while Ochsner and Halpert[5] reported a 2.3% incidence of hepatic hemangioma a half century later. Hemangiomas are most frequently encountered in patients in the third through fifth decades of life, but can occur in any age group. The average age of patients presenting with symptomatic lesions is approximately 45 years.[6] The disease is found most often in females with several series reporting a 4:1 or 5:1 ratio.[7,8] The vast majority of patients are asymptomatic, and most tumors are less than 4 cm in diameter. Multiple hemangiomas, however, have been reported in 9–22% of patients.[5,9] The mean age of our patients (three women, one man) when first diagnosed with a hemangioma was 50.7 years, although symptoms had been present for prolonged periods in each patient prior to diagnosis. Recurrence of hepatic hemangioma was slow and progressive, averaging slightly more than 14 years before upper abdominal symptoms forced these patients to seek medical attention.

Hepatic hemangiomas appear grossly as nodules embedded in the liver substance, red, blue, or gray, depending on the amount of fibrosis; they have a sponge-like structure on sectioning. Histologically, they are composed of large endothelium-lined vascular spaces separated by fibrous septa of varying thickness. Trastek et al.[10] have suggested that enlargement of liver hemangioma was due to ectasia rather than by a new progressive growth of tissue. The recurrent hemangioma in our patients weighed more than 600 g and demonstrated a classic histologic pattern (Fig. 5). Such recurrences could hardly be considered due to mere expansion, dilatation, or distension of preexisting tissue. It would seem that the proper interpretation of the pathologic process is that the extensive recurrence of these hemangiomas is the result of growth of new cellular tissue.

The etiology of hemangiomas of the liver is purely speculative. The vast differences in clinical course that exist between children and adults and the findings of spontaneous regression, growth,[10] and rupture[2] reflect a wide variability in the natural history of this disease.

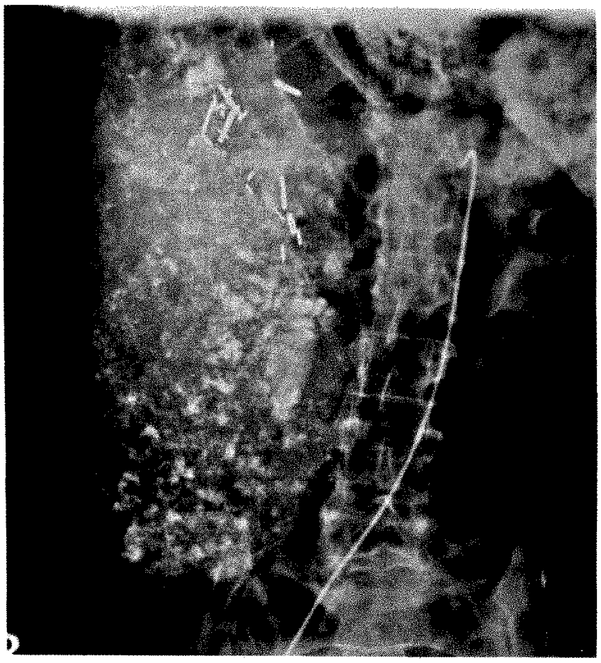

FIG. 4. Angiogram of a giant recurrent hemangioma of the right lobe of the liver.

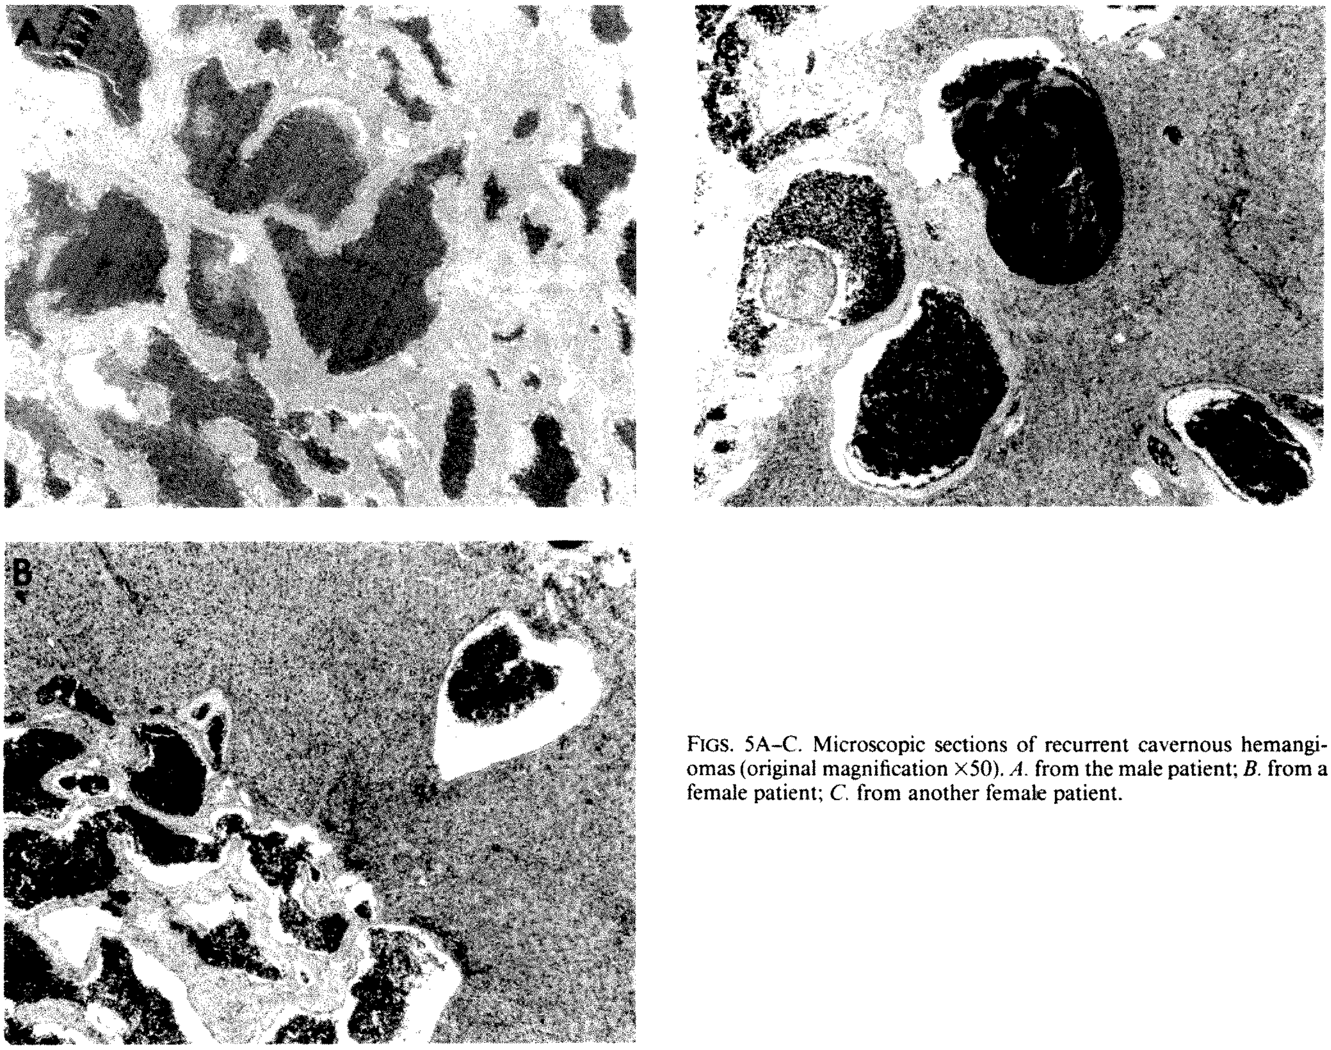

FIGS. 5A–C. Microscopic sections of recurrent cavernous hemangiomas (original magnification ×50). *A.* from the male patient; *B.* from a female patient; *C.* from another female patient.

Several authors suggest that these vascular lesions are benign congenital hamartomas that grow slowly from birth.[5,11] Moore[11] considers hemangiomas to be acquired tumors resulting from areas of focal hepatic necrosis and subsequent regeneration. Robbins[12] suggests that these lesions may be true neoplasms occurring spontaneously and therefore consist of new blood vessels and tissue rather than dilatations of previous telangiectatic lesions.

Baum et al.[13] first called attention to the possible relationship between the use of oral contraceptives and the subsequent development of hepatic tumors. Since that time the literature has reflected numerous reports of the diagnosis of benign tumors such as hepatic adenoma,[14] focal nodular hyperplasia,[15] or hamartomas[16] in women receiving estrogen replacement therapy. Subsequent reports, however, have also documented malignant hepatic tumors in women receiving oral contraceptive steroids.[17,18] Furthermore, it has been suggested that oral contraceptives may affect normal hepatic tissue by inducing hepatomegaly and periportal congestion.[19] The scope of these observations suggests that oral contraceptive steroids may also play a role in the pathogenesis of vascular tumors of the liver.

Klatskin[20] reviewed more than 400 patients with benign liver tumors (hepatic adenomas and focal nodular hyperplasia) and found them to be larger and more prone to hemorrhage and rupture in women receiving oral steroid replacement. He attributed these events to vascular changes and was able to demonstrate a spectrum of findings from minute areas of hemorrhage to multiple, small, diffuse liver hemangiomas. These diffuse hemangiomas (peliosis hepatis) have also been reported in patients given anabolic steroids.[21,22] In addition, Morley et al.[23] have reported rapid growth of a hepatic hemangioma associated with exogenous estrogen administration. Three of the four recurrent hepatic hemangiomas in our series occurred in women who had been receiving oral estrogen therapy prior to their original surgery, and who continued with estrogen replacement until their recurrence was diagnosed. Klatskin[20] and Mays et al.[24] have reported post resection recurrence of hepatic adenoma and focal nodular hyperplasia in patients who continued to use oral contraceptives. The exact role of estrogens in the pathogenesis and natural history of primary or recurrent hepatic hemangiomas is unclear. However, one may speculate that the relationship between estrogens and angiomatous lesions of the skin and gingiva may also exist within the hepatic parenchyma.

These cases of recurrent hepatic hemangioma demonstrate several important features of this disease: (1) the possible association between estrogen replacement therapy and the development of these tumors; (2) the very slow growth pattern of these tumors, measured in decades rather than years; (3) the recurrence of these hemangiomas by growth of new cellular tissue, not by ectasia; (4) has been the effectiveness of radiation therapy in reducing the size of the tumor but not in curing the disease; and (5) the fact that reoperation may be required for recurrent symptoms.

Summary

We have recently treated four patients with recurrent giant hemangioma of the liver. There were three women and one man with an average age on presentation of 50.7 years. Each of the women had been receiving oral estrogen replacement therapy for a minimum of 15 years. Two of the patients (one man, one woman) had received prior radiation therapy as initial treatment. Symptoms of upper abdominal discomfort and pain, nausea, vomiting, and a palpable mass were common on presentation. Three of the four patients underwent surgical resection of giant hepatic hemangioma.

The natural history of primary or recurrent hepatic hemangiomas remains poorly defined. We believe that estrogen replacement therapy may play a role in the pathogenesis of these tumors. Furthermore, operative intervention should be strongly considered in patients who present with recurrent giant liver hemangiomas.

Major Liver Resection for Hilar Cholangiocarcinoma

STIG BENGMARK, M.D., PH.D., HENRIK EKBERG, M.D., PH.D., ANDERS EVANDER, M.D., PH.D.,
BRITTEN KLOFVER-STAHL, M.D., and KARL-GORAN TRANBERG, M.D., PH.D.

From the Department of Surgery, Lund University, Lund, Sweden

Between 1968 and 1984 liver resection with curative attempt was performed in 22 patients with hilar cholangiocarcinoma. Right lobectomy was performed in 4 patients, extended right lobectomy in 7, left lobectomy in 8, and excision of the median segment segment of the left lobe (segment IV) in 3. Bilio-enteric continuity was restored by hepatocholedochostomy in 17 patients and hepatojejunostomy in 4. (One patient had external transhepatic catheter drainage and no internal bile drainage.) Operative mortality rate was 27% and caused by excessive intraoperative bleeding, sepsis, or liver insufficiency. Postoperative complications occurred in 57% of patients surviving the operation and were due mainly to leakage from the hepatocholedochostomy. Median survival was 6 months, and one third of the patients survived 1 year. Three patients survived 10 years and were among the four patients in whom a tumor-free resection margin was obtained (one of them died in the postoperative phase). It is concluded that resection of hilar cholangiocarcinoma may give long-term survival if a free resection margin is obtained. The importance of a free resection margin indicates that surgery should be aggressive and include liver resection.

RESECTION IS THE ONLY TREATMENT that offers a hope for cure of bile duct cancers. However, operative morbidity and mortality rates have been high, and long-term survival has been exceptional. This is true especially for hilar cholangiocarcinoma described by Altemeier et al.[1] in 1957 and by Klatskin[2] in 1965. Although this tumor is rare, it should be recognized that it has an annual incidence of about 1300 in the United States.

In his review of the literature in 1983, Boerma collected a total of 75 cases of local resection of hilar cholangiocarcinoma.[3] Operative mortality rate was 11%. Mean survival was 19 months, and there was no 5-year survivor. Local recurrence was the usual cause of death. It may therefore be assumed that curative resection should include resection of adjacent parts of the liver.

The first one-center series of liver resection for hilar cholangiocarcinoma that comprised more than ten patients came from our group in 1980[4] and was soon followed by four other reports. Tsuzuki et al.[5] reported 15 cases with a 50% actuarial survival of 24 months and a longest survival of 3 years and 8 months. Blumgart et al.[6] reported 12 liver resections with a mean survival of 17 months; seven of their patients were alive at the time of the report. Langer et al.[7] performed 12 resections of high bile duct tumors, and all or most of them included liver resection. They reported a mean survival of 28 months and two 5-year survivors who later died of recurrent disease. In a series by Mizumoto et al.[8] 13 hepatic resections were followed by a mean survival of 12 months: the longest survival was almost 6 years in a patient having undergone right lobectomy.

The present paper summarizes our experience from 22 consecutive liver resections for hilar cholangiocarcinoma during a 16-year period.

Materials and Methods

Patients

Twenty-two patients with hilar cholangiocarcinoma underwent a combined bile duct and liver resection between 1968 and 1984 (Fig. 1). There were 13 men and 9 women with a median age of 56 years (range: 33–68 yr). Fifteen patients were referred from other hospitals; one patient had undergone cholecystectomy 30 years earlier.

All patients were jaundiced at operation, but none had been jaundiced for more than 2 weeks before diagnostic procedures were started. Common complaints were pain (64%), loss of appetite (59%), weight loss

(50%), and fatigue (41%). Six patients had experienced minor symptoms from the upper right quadrant for many years.

Preoperative Investigations and Management

The results of various diagnostic procedures are summarized in Table 1. Percutaneous transhepatic cholangiography (PTC) was used in 13 patients. The catheter was left for bile drainage in 11 cases but failed in 3, in whom bile leakage, cholangitis, or suspicion of visceral perforation led to emergency laparotomy and replacement with T tube drainage.

Exploratory laparotomy was the initial diagnostic procedure in nine patients. It was performed only once after 1979 when diagnostic procedures such as ultrasonography, computed tomography (CT), and endoscopic retrograde cholangiopancreaticography (ERCP) were available. Surgical exploration ended in T tube drainage in four patients and a radical procedure in one, whereas three patients underwent a subsequent PTC. Seven of the exploratory laparotomies were performed at other hospitals before referral to us.

Arteriography was performed in all but the first three patients. It was used to assess resectability by identifying major involvement of the hepatic artery and the portal vein, or involvement of both the right and left branches of the portal vein. Angiography was valuable for planning the resection in 11 patients; in the remaining eight no abnormalities were seen.

Percutaneous fine needle aspiration biopsy, guided by PTC or angiography, was performed in nine patients. A positive diagnosis of cancer was obtained in seven patients.

Tumors were considered unresectable when they encased the proper hepatic artery, the main trunk of the portal vein, both the right and left branches of the portal vein, or when they extended beyond the second bile duct confluence bilaterally.

The bile ducts were drained before resection in 15 (68%) patients for a period of 24 days (median) (range: 11–76 days). Eight patients had percutaneous transhepatic drainage, and seven patients were drained through a tube inserted during surgery.

Pathology

The size of the primary lesion varied between 2 and 5 cm. The distal extension of the tumor included the cystic duct in five patients but was otherwise restricted to the main hepatic duct.

In order to describe the antomic location and the pattern of growth of the tumors, we have modified the classification of Bismuth and Corlette.[9] Since it appears that tumors that extend into the right or left duct may be

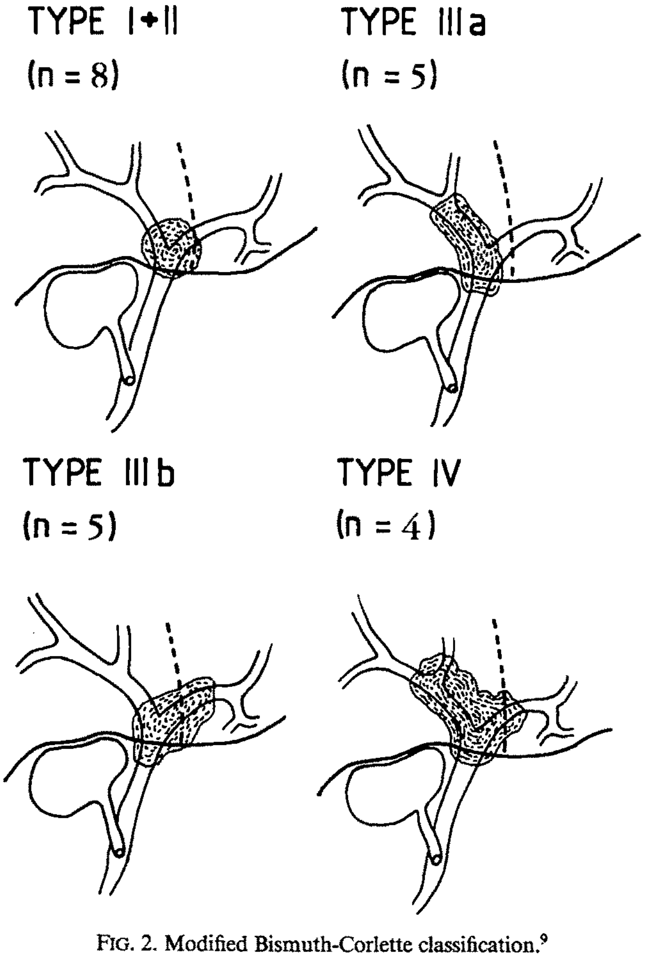

FIG. 2. Modified Bismuth-Corlette classification.[9]

	Extended right lobectomy + hepatojejunostomy	2

Lig RHD = ligation of the right hepatic duct.

treated differently because of the different anatomy, we have subdivided type III into two types (Fig. 2): type IIIa, extension into the right but not the left duct; and type IIIb, extension into the left but not the right duct. Type IV denotes tumor growth into both the right and the left hepatic ducts. Eight tumors were located at the hilum with minor extensions into the hepatic ducts (type I + II). Extension along the right (type IIIa) or the left (type IIIb) hepatic duct dominated in five cases each. Tumor growth along both hepatic ducts (type IV) was seen in four cases (Fig. 2).

Six patients had tumor growth into the adjacent liver parenchyma, and another six had unilateral liver metastases. Regional lymph node metastases were present in four patients.

Microscopic examination of the resection margin demonstrated no evidence of disease in 4 (18%) patients, equivocal findings in 5 (23%), and tumor growth in 13 (59%).

Surgical Procedures

The surgical procedures are summarized in Table 2. A midline incision was used during the first half of the study period but was later replaced by a right-sided transrectal approach. Thoracotomy was performed in two patients. All lymph nodes in the hepatoduodenal ligament, around the coeliac axis, and at the liver hilum were removed for microscopic examination. Inflow vessels in the liver hilum were ligated before resection of the liver in half of the patients.

Patients with a type I + II tumor underwent left or right lobectomies or resection of the median segment of the left lobe (segment IV). Left lobectomy was performed in all patients with a type IIIb tumor. Type IIIa and IV tumors were removed with simple or extended right lobectomies. Cholecystectomy was performed in all patients.

Reconstruction was done as an end-to-end biliary-biliary anastomosis (N = 17) or as an end-to-side biliary-enteric anastomosis on a Roux-en-Y loop (N = 4). Reconstruction was considered technically impossible in one patient who was managed postoperatively with percutaneous transhepatic drainage alone. Preoperatively placed PTC catheters were left for drainage after surgery. Patients without preoperative bile drainage received a T tube or a transhepatic drainage catheter during the operation. No patient received chemotherapy or radiotherapy.

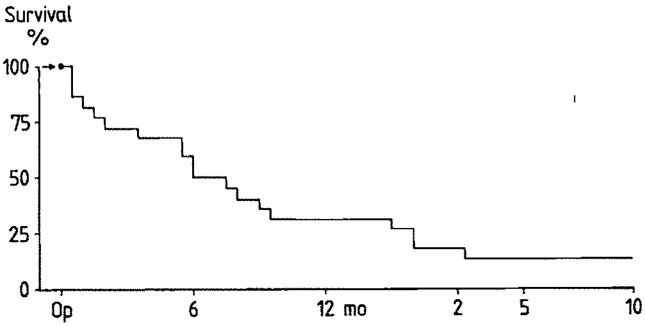

FIG. 3. Survival rates.

Results

Survival (Fig. 3)

The overall median survival was 7 months (range: 0–170 months). Excluding operative deaths (N = 6), survival was 9 months (median) (range: 4–170 months).

Seven (32%) patients lived for more than a year. Four of them survived 1.5 to 2.5 years. The remaining three patients lived for more than ten years after resection; 2 of them were alive after 10 and 11.2 years, respectively, while the third patient died of recurrent disease after 14.3 years. Except for deaths caused by surgery, all deaths were due to recurrent disease.

A resection margin free of tumor had a major impact on survival. The three patients surviving for more than 10 years had a resection margin free of disease, whereas none of the others had (except for one patient who died from the operation). Two of the three 10-year survivors had involvement of adjacent liver parenchyma, and two of the patients surviving more than 1 year had ipsilateral liver metastases. The presence of liver metastases, growth into the liver parenchyma, or the type of operation did not vary with prognosis. Spread to lymph nodes in the hepatoduodenal ligament was always accompanied with a poor survival (less than 1 year).

Recurrence

Fourteen patients died of recurrent disease, situated in the liver hilum or the liver parenchyma in all but one. The time for detection of local recurrence varied from 2 months to 9 years (median: 5 months). Liver metastases were demonstrated in two patients, after 2 months and 13 years, respectively. Peritoneal secondaries were found in five patients and bone metastases in two patients.

Nine patients underwent reoperation because of recurrence: atypical liver resection (1), resection of a large extrahepatic tumor (1), biliogastric anastomosis (1), hepatojejunostomy (1), placement of an internal splint (3), T tube placement (1), and exploratory laparotomy (1). Two of the reoperated patients died during the postoperative hospitalization. Five patients with recurrent biliary obstruction did not undergo reoperation but received a percutaneous transhepatic catheter for drainage of bile.

The presence or absence of abnormal vessels at angiography did not help in predicting whether or not the resection was microscopically radical; resection was microscopically radical in 2 of 11 patients with abnormal findings and in 2 of 8 patients with no abnormalities.

Complications

Six patients died from the operation, an operative mortality rate of 27%. The main causes of death were intraoperative bleeding, liver necrosis, and infection (Table 3). There was no change in operative mortality rate during the study period.

Major complications occurred in 9 (56%) of the 16 patients who survived the operation (Table 4). Most of them were related to leakage from the hepatocholedochal or hepatojejunal anastomosis. Liver insufficiency developed in a patient who underwent an 85% hepatectomy. Following right lobectomy, the remnant liver rotated in one patient and caused occlusion of the hepatojejunostomy. The patient receiving a transhepatic catheter for drainage of bile (and no biliodigestive shunt) had several episodes of cholangitis.

TABLE 3. *Operative Mortality Rates*

Cause of Death	Length of Survival (d)
Intraoperative bleeding and coronary infarction	2
Intraoperative bleeding and multiple organ failure	3
Liver necrosis and failure	12
Leaking hepatocholedochostomy	27
Liver necrosis and failure	42
Subphrenic abscess and bleeding duodenal ulcer	47

Four patients had no preoperative drainage of bile. Two of them died from major intraoperative bleeding whereas the other two had an uneventful postoperative course.

Discussion

Bile duct tumors should be regarded more as regional than local. Since bile ducts have thin walls, a biliary tumor is apt to involve surrounding tissues. It spreads along the periductal lymphatic network, perineural lymph clefts, and periductal venules and arterioles and may infiltrate the bile duct wall submucosally over a wide distance.[10,11] Regional or hepatic metastases may be expected in 30–50% of the cases.[3] Distant metastases are otherwise quite infrequent, appear late, and are usually located in the lesser omentum and occasionally at other sites within or outside the abdominal cavity.

The first attempt at local resection seems to have been described by Brown and Myers in 1954.[12] However, before 1973 and the early work of Longmire et al.[13] at-

tempts at resection were exceptional and tumors discovered at laparotomy were only intubated, if possible. Most patients received no treatment and only limited diagnostic work-up. The pessimistic attitude was summarized by Blumgart et al.[6] caused by difficulties in the following: (1) preoperative diagnosis; (2) histologic confirmation; (3) excisional therapy; and (4) creation of a reliable bilio-enteric anastomosis. However, the situation has changed dramatically in recent years because of the availability of modern imaging methods and the improvements of surgical technique.

It has been repeatedly emphasized that tumor cells often remain after a macroscopically radical resection. Beazley et al.[14] were able to get free margins in 7 out of 16 resected cases, most of whom had undergone liver resection. One would expect the risk of residual cancer to be even greater after local resection alone. This view is substantiated in a report of Mizumoto et al.[8] in which a free margin was achieved in only 1 of 11 locally resected cases. Local recurrence has also been the main cause of death when resection of the quadrate lobe has been added to the local resection of the confluence, and no 5-year survivor has been reported.[3] Thus, resection of the bifurcation, alone or with quadrate lobe resection, is likely to leave cancer cells at the margin and to add little to the prospect of a good prognosis. Residual cancer increases the risk of early complications related to poor healing of the biliary-enteric anastomosis: leakage, abscess formation, sepsis.

Early reports indicated that high bile duct tumors are more common in the left, or the left part of the confluence, than in the right duct.[15] There is no support for such an opinion in the study of Weinbren and Mutum,[16] who found tumors on the right side in 21% and on the left side in 11% of their cases. As noted by Longmire et al.[13] the opinion of left side predominance probably reflected the fact that right-sided tumors were regarded as intrahepatic or untreatable. Most early attempts at liver resection were thus on the left side. However, the possibility of performing a radical resection and getting a reliable hepatojejunostomy is better when the tumor is situated on the right side. The right hepatic duct has a maximum length of 1 cm, which means that the tumor usually extends beyond the secondary confluence. The comparatively long left duct offers better possibilities for radical resection on the right side and has led to an increased number of right lobectomies. Most of our recent patients were operated with extended right lobectomies as were 9 (75%) of 12 cases of liver resection reported by Blumgart et al.[6] This approach is supported by the recent study of Mizumoto et al.[8] who demonstrated that about half of the patients have direct invasion of hepatic parenchyma at the hilum and that a similar number of patients have invasion of bile ducts draining the caudate lobe or direct invasion of caudate lobe parenchyma. It follows that the caudate lobe should be removed together with extrahepatic bile ducts and adjacent liver parenchyma. A tumor located at or close to the right hepatic duct should be resected with an extended right lobectomy to ensure complete removal of the caudate lobe and process. The chances of radically excising a tumor situated in the left duct are somewhat smaller because left lobectomy, or extended left lobectomy, does not ensure complete removal of the caudate process.

Most postoperative complications are related to leakage of the anastomosis between the hepatic ducts and the distal common bile duct or a jejunal loop. Like other authors,[5,6] we have abandoned biliary-biliary anastomosis in favor of hepatojejunostomy (on a 60-cm long Roux-en-Y loop) since it appears to carry a lower postoperative morbidity rate and increases the possibility of a radical resection.

Modern palliative measures include percutaneous, endoscopic, or surgical intubation and are accompanied by a 30-day mortality rate of roughly 30% and frequently by a poor quality of life.[6,7,17-19] Comparison with biliary-enteric bypass, with or without resection, is difficult because of differences in attitude and patient selection, but it is often noted that the quality of survival is good after surgery and appears better than after intubation alone.[6,7]

In summary, we believe that hilar cholangiocarcinoma in a patient fit for surgery should be carefully assessed with respect to a resection procedure, which in most cases should include liver resection. This attitude is based on the difficulty in obtaining a free resection margin if less radical procedures are used. It is also based on the potential for cure or long-term palliation with a good quality of survival and the fact of poor survival and quality of life with other surgical procedures or with intubational techniques.

Blunt Trauma to the Liver

Analysis of Management and Mortality in 323 Consecutive Patients

EVERARD F. COX, M.D., F.A.C.S., LOUIS FLANCBAUM, M.D., F.A.C.S., ALTON H. DAUTERIVE, M.D., and RICHARD L. PAULSON, M.D.

This study represents a 6 year 4 month experience with blunt trauma to the liver of patients from the Maryland Institute for Emergency Medical Services Systems, a major regional trauma center. The significance of this study is that it describes a large, relatively homogeneous population and analyzes what the state of the art for liver trauma has been in a center dedicated solely to trauma that has a full-time staff of trained traumatologists. Three hundred twenty-three consecutive patients with blunt liver trauma are presented, representing 3.5% of 9271 patients admitted to the institute over the period of this study. Ninety per cent had associated traumatic injuries requiring operative intervention. A mortality rate of 31% (101 patients) was noted; 41.5% of the deaths, due primarily to liver injury, occurred intraoperatively during the initial operation following admission. The use of simple suture techniques and resectional debridement to control hemorrhage are advocated. Anatomic lobectomy, intracaval shunting, and hepatic artery ligation were uniformly unsuccessful. The use of drains was associated with a significantly increased incidence of infectious complications ($p < 0.00002$).

> "Rupture of the liver is fortunately an accident not often met with but one which, when it is seen, may be associated with a condition of the patient as serious as anyone can meet in the surgical practice. While small lacerations of the liver substance may be, and no doubt are, recovered without surgical interference; if lacerations are extensive and vessels of any magnitude are torn hemorrhage will, owing to the structural arrangement of the liver, go on continuously and by the time such a patient comes under the care of a surgeon, the general state is almost invariably bound to be extremely grave from the hemorrhage alone or from hemorrhage and shock combined. This is perhaps especially the case in that class of injury due to *contusing* violence in which there is often gross injury inflicted on parts other than the liver and when shock is liable to be more severe than in localized injuries caused by sharp instruments" (J. Hogarth Pringle, 1908)[1]

From the University of Maryland, Maryland Institute for Emergency Medical Services Systems, Department of Surgery, Shock Trauma Center, Baltimore, Maryland

IN THE INTERVENING YEARS since Pringle's *notes* on hepatic trauma, the surgeon's frustration in managing serious "contusing" injury to the liver along with the mortality rate associated with it has remained virtually unchanged. Numerous large series dealing with the management of complex hepatic trauma have been reported. Most of these have come from large urban trauma centers treating a large percentage of penetrating injuries. Often the liver injury is an isolated one, and associated extra-abdominal injuries are not present. In contrast, this study represents the experience gained over a 5-year period ending in 1985 from 323 consecutive patients with liver injury caused exclusively by blunt trauma treated at Maryland Institute for Emergency Medical Services Systems, Shock Trauma Center, a regional center for major trauma. It is a combined experience of an institutional staff of trauma surgeons.

Patient Profile

There were 211 males (65%) and 112 females (35%) comprising 3.48% of 9271 patients admitted during this period. The average age was 29 years. Automobile accidents accounted for 79%, motorcycles 10%, and pedestrians 8% of the injuries. The remaining 3% resulted from industrial, farm, or home accidents. Thirty per cent of these patients had abnormal elevation of their blood alcohol on admission. Except for a few patients from the immediate urban center who came by ambulance, the majority of these patients were transported directly from the scene of the accident by helicopter and

transferred to the admitting area where immediate resuscitation, diagnostic evaluation, and management protocols were instituted by full-time traumatologists. Any patient who had injury to other systems, namely, closed head injuries, fractures of the skeleton, blunt chest injury, maxillofacial trauma, or extensive soft tissue contusion that could require a prolonged general anesthesia during their care, or who may have been unable to react reliably with normal physical signs because of inhibition by alcohol or other drugs, or were hemodynamically unstable, as well as those with clinical signs that led to the suspicion that there was organ injury within the abdomen, were subjected to diagnostic peritoneal lavage. The diagnosis of hemoperitoneum was established using diagnostic peritoneal lavage alone, except in seven instances wherein the urgency of the patient's condition precluded it and *diagnostic* celiotomy was carried out. Another four patients were transferred from other hospitals after celiotomy disclosed liver injury deemed beyond the capability of those facilities. With an occasional exception, criteria for celiotomy was 50,000 red blood cells/mL^3 in the effluence of the diagnostic lavage.

Results

Group I-S (Table 1) consisted of 120 survivors (37%) who in the opinion of the operating surgeon required no surgical intervention to the liver at the time of the celiotomy. Injuries in this group were described by the surgeons as minor capsular tears, minor lacerations, lacerations with clots in place, not bleeding, or bleeding controlled with pressure, *etc.* In analyzing these patients other distinctive features became apparent. Ninety-seven patients (81%) were hemodynamically stable at the time of admission, with systolic blood pressure greater than 90 mmHg and pulse less than 110/min. An average of 3 units (U) of blood was given during the admission and perioperative periods. The use of drains was studied as related to complications, slightly more than half (56%) had no drains. The average stay in the hospital was 15.15 days, excluding patients with prolonged stays for closed head injury or complicated orthopedic problems.

The 60 patients in group II-S (Table 2) (18.5%) were treated using simple surgical techniques such as the placement of simple or mattress sutures, topical hemostatic agents, or both. They were slightly less hemodynamically stable (75%) than those patients in group I-S and required an average of 6 U of blood during the resuscitative and perioperative periods. Two thirds were not drained, and a one day longer hospital stay was recorded for these patients.

Forty-two patients (13%) were assigned to group III-S (Table 3). Patients so designated were more severely injured and required more aggressive surgical measures. Seventy-four per cent of these patients were hemodynamically unstable at the time of admission. Three fourths had associated extra-abdominal injuries, including thoracic in 26 patients, orthopedic in 16 patients, maxillofacial in 13 patients, and neurologic in 11 patients. Associated abdominal injuries, spleen in 16 patients, pancreas in 4 patients, bowel in 3 patients, gallbladder in 3 patients, and diaphragm in 2 patients occurred in half of the patients. The clear difference from survivors in groups I-S and II-S appeared to be the amount of blood replacement. Excluding one patient who used 100 U of whole blood, an average of 22 U of PRBCs per patient was given. Fresh frozen plasma was used liberally in this group of patients to enhance blood clotting. Drains were not used in 30% of this group. The hospitalization increased to 24 days if two patients with prolonged stays are excluded. The only three survivors of hepatic artery ligation are in this group. Fifteen patients had some degree of liver resection, limited in all instances to resectional debridement of the injured fragment of the liver. Suture technique was the most often used and most effective method of gaining control of the hemorrhage. One patient was treated successfully with packing only of a major liver injury. Thirty of the 42 patients in this group recovered without complications related to the abdomen.

The 17 patients (5.26%) in group I-D (Table 4) were clinically similar to those in group III-S except that they died. Though the liver was considered to be a major factor in the death of these patients, this is primarily based on the impression that the extensive blood loss from the liver and the accompanying shock aggravated the recovery of other organ functions. Excluding two patients with 105 days and 125 days, respectively, the interval between injury and death in these patients averaged 12.5 days. Seven patients had either the right or the left hepatic artery ligated and in one patient the common hepatic artery was ligated. Death in this group of 17 patients often followed the sequence of fever, increased cardiac output, and peripheral vasodilatation characteristic of sepsis, resulting in progressive multiorgan failure and eventual death, or failure to control the liver hemorrhage in the face of refractory coagulopathy.

Group II-D (Table 5) includes 42 patients (13%) who died intraoperatively because of failure to control the bleeding from a severely injured liver. All had associated major injuries requiring operative treatment. Thirty-seven patients had 49 extra-abdominal injuries including severe crushing chest injuries (*i.e.*, lacerated lung, myocardial contusion, and ruptured diaphragms in 23

patients). In 13 patients closed head injury may have been as grave as the liver injury, but it was deemed the liver injury alone would likely have been fatal. Concurrent abdominal injuries were present in 17 patients including spleen in 12 patients, bowel in 5, and kidney, bladder, and gallbladder in 1 patient each. Only two of these patients were hemodynamically stable on arrival in the admitting area. Twelve patients (29%) arrived in the admitting area with no obtainable blood pressure, and 11 had systolic blood pressures < 70 mmHg. In those 27 patients in whom prothrombin time studies were available at the time of admission, there was a marked prolongation (greater than 3 seconds over control) in 21 (75%). These injuries were described as deep stellate lacerations or transections, 34 (81%) primarily involving the right hepatic lobe. In 16 patients (38%) the injury involved the major hepatic veins or retrohepatic vena cava. Intracaval shunting of the inferior vena cava was unsuccessfully attempted seven times. The common hepatic artery was ligated twice and the right hepatic artery twice. On seven occasions formal anatomic resections of the right lobe were initiated. Twelve patients expired while attempts were made to compress the liver in order to achieve hemodynamic stability, and six patients expired before any attempt at control could be made.

Group III-D (Table 6) contains deaths primarily associated with injuries to other organ systems. It is noteworthy that 24 of these patients were female, a sex ratio of 0.75:1 (M:F). From the data available for this study, there is no clear reason for this skewed statistic. The position of the victim in the vehicle was studied with no significant finding between driver and passenger. These 42 patients (13%) are predominantly patients with closed head injury and an incidental liver injury, which was insignificant. Fatal head injury occurred in 33 of these patients and was a major contributing factor in an additional nine patients. Severe chest injury was also prominent. Eighteen of these patients (43%) died in the operating room or on the day of admission, and 76% died within the first week.

Two hundred forty patients were studied regarding the use of intra-abdominal drainage; the 42 patients who died on the operating table and 42 who died from injury unrelated to the abdomen were excluded. Intra-abdominal drainage was established in 116 (48%), and no drainage was used in 124 (52%) (Table 7). These usually consisted of either penrose or sump drains, or a combination of both, brought out through separate wounds. The infection rate in the 116 patients who were drained was 22% *versus* a 4% rate in 124 patients not drained (p < 0.00002, Fisher's exact test, two-tailed). The instinct because of traditional training of most surgeons has been to use drains in the more severely injured patients, which is also reflected in this study. Of the 17 patients who died late, (group I-D) all but three were drained. There was infection in four of the 14 patients drained and in one of the three not drained (NS). Of the 43 patients with severe liver injury that survived (group III-S), 29 were drained and eight had complications likely associated with prolonged drainage. The 14 patients not drained had no complications (p < 0.04). In the 180 patients with minor liver injury (groups I-S and II-S), 14 patients had infections attributable to drains *versus* four infections in the undrained patients (p < 0.02). The theoretical occurrence of bile peritonitis or collections of intra-abdominal bile did not occur and T tube drainage of the common bile duct was not used.

In this study of 323 patients with injury to the liver that varied from incidental and insignificant to severe and fatal, 101 died, a 31.12% mortality rate. A more accurate perspective of the magnitude of the problem of management of severe blunt liver trauma can be appreciated if the 180 patients without significant liver injury (groups I-S and II-S) are excluded from the study, and the 42 patients with minor liver injury that died from the associated injury are not included (group III-D) in the total of 222 patients. Among the 101 remaining patients with severe liver injury there were 42 survivors (group III-S). There were 17 late deaths (group I-D) and 42 patients (group II-D) who died during the operation because of failure to control the hemorrhage from liver injury. These 101 patients were the patients with liver injury that were theoretically salvageable at the time of admission. Thus, the mortality rate for the liver severely injured by blunt trauma in this study is 58.4%. However, the 17 late deaths (group I-D) of those with severe injury from blunt trauma represent a mortality rate of 5.26% of the total 323. Many of the 42 intraoperative deaths and the 42 deaths from associated injury (groups II-D and

III-D) realistically and probably had little chance for survival at the time they were admitted. It is the operative management of the bleeding liver in these patients that is the real challenge to those treating severe blunt liver trauma and provides the focus of this study.

Discussion

Myriads of measures to deal with serious liver injury have been proposed, used, studied, and reported by respected investigators from outstanding institutions worldwide. No one surgical technique has emerged that is clearly superior and applicable to every patient. Each has proponents, and when expertly applied in the correct situations will have rewarding results.

Suturing

Suturing the liver has been condemned by Lim et al.,[2] and according to Mays[3] is based on tradition only. Trunkey, et al.[4] reporting on 811 patients, noted that 20.4% of their patients with extensive laceration of the liver were treated using 0 to number 1 catgut interlocking horizontal mattress sutures. During the latter part of their study bleeding points were managed by direct suture ligation. It was thought that this reduced the chance of necrosis and hemobilia. Only 21.3% of the 811 patients they reported were victims of blunt trauma.

In this study suturing the liver as described above, with variations according to the operator's perference, was the technique most often used. All of the 60 patients in group II-S and 26 of the 42 in group III-S were treated using various suturing methods. In blunt trauma, where two fragments of liver gape apart and where point ligation of the bleeding vessels would require manipulative intervention, often difficult because of poor exposure and the technical maneuvering that adds to the trauma already present, this simple, quick, traditional method was effective in limiting blood loss. We experienced none of the complications often alluded to (*i.e.*, hemobilia or liver necrosis in the survival group) when sutures were used. Lucas and Ledgerwood[5] noted that "contrary to theoretical objections that liver sutures will cause hepatic ischemia . . . no patient died following liver suture for control of bleeding," only 9% of the patients in that study were victims of blunt injury.

Liver Resection

Successful liver resection in 15 surviving patients in group III-S was limited to removal of the injured fragments peripheral to the fracture line of the liver. *Resectional debridement, completion resection,* and *segmentectomy* were terms used to describe these procedures. Two patients required reoperation for bleeding and were treated with additional ligations of the right hepatic arteries. Both patients developed abscesses, presumably related to the relative ischemia of the liver. Major liver resection along anatomic planes advocated by many[6-11] was attempted nine times and was never successfully accomplished with a survivor (group II-D). Each of these nine patients was stable prior to the commencement of the attempted formal resection, and as the procedure progressed the bleeding became uncontrollable. Mays[3] in his monograph on hepatic trauma, referring to the use of anatomic lobectomy in acute liver injury states "the mortality rate forbids it." Pachter and Spencer[12] noted a mortality above 50% and observed "though the techniques of hepatic resection have been well defined there is declining frequency in its use." The present experience here with blunt trauma substantiates these warnings.

Intracaval Shunting

Schrock et al.[13] described the use of an intracaval shunt of the inferior vena cava in a victim of a fall with avulsion of the hepatic veins and a lacerated retrohepatic inferior vena cava. Since that report Doty and Berman[14] and Brajendranath et al.[15] among others have added technical refinements in search of the best approach to achieving vascular control when injury to the liver extends into the retrohepatic vena cava or the hepatic veins. Some authors oppose intracaval shunting. Yellin et al.[16] advocate venous isolation with occlusion of the inflow to the liver. Balasegaram[17] had eight survivors in 12 patients with *juxtahepatic venous* injury using venous isolation and contends that sternotomy to gain exposure takes too much time in these desperate circumstances. Regardless, if access to the suprahepatic vena cava is necessary, sternotomy easily allows the quickest exposure with the least postoperative morbidity rate.

Intracaval shunting was used in seven patients (group II-D) without a survivor. All three approaches usually described for the insertion of the shunt were utilized. Patients with these injuries generally do not do well in spite of isolated reports of successful use of either of these methods.[18]

Ligation of Arterial Inflow

In 1933 Graham and Cannell[19] postulated that operative interruption of the hepatic artery could be successfully done without interfering with liver viability. Hepatic artery ligation was briefly in vogue as a treatment for cirrhosis after being introduced by Rienhoff[20] in 1951. Madding[21] in 1954 suggested that hepatic artery ligation be "used in some cases of liver injury." Mays[22,23] has recently promulgated *dearterialization* of the liver in severe injury with certain limits in selected patients. Others[24–26] also saw a place for its use. Still others, Pachter and Spencer,[27] see it as an unnecessary hazard for the patient and it is without clear rationale.

In this review, two patients with right hepatic artery ligation and one patient with ligation of the proper hepatic artery survived (group III-S). There were also four patients with hepatic artery ligation among those that died intraoperatively (group II-D). Of the 17 late deaths from liver injury (group I-D), seven had hepatic artery ligation. Both surviving patients with right hepatic artery ligation required reoperation for continued bleeding. The third survivor with ligation of the proper hepatic artery had an uncomplicated recovery and was discharged in 21 days. The records here show one unqualified success in 14 patients with hepatic artery ligation.

Omental Packing

Stone and Lamb[28] described the use of an isolated omental pedicle placed into the fracture defect and held in place by sutures. An updated report by Fabian and Stone[29] described their experience with 115 patients in which this method of packing to obtain hemostatic control was successful 90% of the time. The experience in this study with omental packing is limited to one patient (group III-S) where it was successful.

Packing with Gauze

A last desperate measure to control bleeding from the liver, packing with gauze, has recently under certain conditions been proposed as a deliberately planned first approach.[30,31] Packing with radiopaque laparotomy pads was used on six occasions, three times in the survivors' group without complications, and three times in the late death group. Two of the late death group developed infection and sepsis before they died.

Drains and Complications

The association between the use of intra-abdominal drainage and infection was analyzed (Table 7). While the traditional teaching of most surgeons is that drainage of hepatic injuries is necessary in order to avoid bile peritonitis and abscess formation, these data do not bear this out. The incidence of intra-abdominal infectious complications was significantly greater in those patients who were drained compared to those who were not ($p < 0.00002$). This may be related to the fact that the mechanism of injury in this series was blunt trauma rather than penetrating trauma, and, therefore, the operative field was less likely to be contaminated. While there are situations encountered in these kinds of patients that may dictate the use of drainage, from this study the evidence against routine use of drains in blunt liver trauma would support those who believe it is not necessary, especially in situations of insignificant liver injury.[32,33]

Conclusions

Though the data presented in this study has been subjected to retrospective analysis, it was accumulated in a prospective fashion. Specific management trials were to be scrutinized and documented. Was hepatic artery ligation helpful? Was major hepatic resection useful? Could intracaval shunting be successfully used? What about drains? Does packing have a place? When does coagulopathy and/or hemodilution become irreversible? These among other questions formed the basis to begin this study; as the data were collected and analyzed on a yearly basis other problems in the care of the liver injured by blunt trauma became apparent.

Before the study began it was clear that serious injury to the liver was a difficult condition, and both the surgical team and the patient had usually encountered a desperate situation. There was no concensus among the staff as to the best approach to these problems. As the foregoing material indicates, the entire spectrum of known technical approaches have been utilized with varying degrees of success and without decisive results favoring any one approach. As each success or failure was encountered and documented, there was a gradual realization among the staff that the more aggressive approaches were most often futile, and there was a trend toward less bold surgical measures. The attending surgeons became less inclined to attempt formal anatomic resections. Hepatic artery ligation, at times a technical challenge itself, did not always stop the bleeding and there were no instances where intracaval shunting was successful. Though these heroic measures have had persuasive advocates, the impression in the literature that these are simple procedures that can simply be accomplished in instances of severe liver trauma is misleading and has at times contributed to a novice, machismo approach to major liver trauma.

The liver injured by blunt trauma and the associated injury, both extra-abdominal and abdominal, when it occurs creates a clinical entity requiring special considerations and the best in clinical judgment and surgical management. Severe blunt trauma must be considered a specific disease. There are few conditions that acutely alter the entire physiology as does blunt trauma in its most serious forms. The mortality rate from liver trauma bears a linear relationship to the severity of the injury and an inverse relationship to the experience, judgment, and skill of the team caring for the patient. These disasters seem to occur at night and on weekends. Since the best results reported come from institutions where one doctor concentrates on the liver only, or a liver team is organized, it may occasionally be well to stay the definitive execution of care (or pack the injury) until such a team can be assembled.[34]

On admission most of these patients with severe liver injury will have gross blood return on diagnostic peritoneal lavage. They will usually be hemodynamically unstable as was seen in this study. Before attempts to treat specific organ injury are begun, effective restitution of cellular oxygenation must be accomplished through respiratory and cardiac support by whatever means are required. In most instances severe liver injury will become the priority consideration in the management of the severely injured trauma victim.

At operation, minor injuries need little or no treatment. The more severe injuries graded toward those with retrohepatic vena caval injury or hepatic vein involvement require only those measures needed to control bleeding. From these data the great majority can be controlled with simple sutures placed 2 to 3 cm from the edge of the fracture with an absorbable suture using a blunt point needle with a large arc placed in whatever fashion the operator is comfortable with. The anxiety about intrahepatic hematoma, hemobilia, necrosis along the suture line, bile collection, and biliary fistulae appear to be unwarranted; they did not occur in this series. The more peripheral these injuries are, the better. These simple methods work, and if done with a minimum of meddling, will save blood and time. Drainage of the abdomen in these relatively minor injuries does not appear warranted in lieu of the increased incidence of infectious complications.

In the surgical management of fragmentation fractures where the viability of distal segment of the liver is questionable, resectional debridement is all that is necessary or should be attempted. Formal or anatomic lobectomy should not be attempted, and hepatic artery ligation is rarely helpful. Bleeding points should be individually controlled by suture ligatures in preference to hemoclips or cautery since repeated *mopping* with gauze tends to pull off the clips and abrade the eschars of the cautery. These procedures can be tedious and time-consuming. Impatience and continuing to operate in the face of persistent bleeding is not often rewarded by a successful outcome. The patients must be hemodynamically stable, if possible, before any attempts at technical maneuvering are accomplished. For deeper, more central injuries, if bleeding is arterial or is too great to ignore, control at the porta hepatis using Pringle's maneuver and widening the *hepatotomy* to control the bleeding vessels with point ligations may be necessary. In addition, compression of the liver injury to control the bleeding while waiting for the replacement of blood and clotting factors seems an easy thing to do but is often ignored. When there is a blood clot in the fracture fissure, it is a good idea to *dry up* the area and ascertain the degree of bleeding and if possible, in good judgment, to leave it alone before the curiosity to probe the depth of the wound becomes a hazard. In these kinds of lesions packing with laparotomy pads carefully placed between the liver and the diaphragm and then stabilized with several packs in the subhepatic space will often be sufficient treatment. No drains are used, and after several days when the patient has been stabilized, the packs, residual blood, and debris are removed at reoperation. Though the experience in this study with omental packing is nil, there are some sound theoretical considerations for its use.[28,29] Again, even in these large injuries (groups III-S and III-D), bile-related complications did not occur and the incidence of infectious complications associated with the use of drains was significantly increased ($p < 0.01$).

Data accumulated on blood coagulation in this study indicate that coagulation factors were depressed in the majority of the severely injured patients. After patients with suspected severe liver injury are admitted, and as soon as possible during the resuscitative process, fresh frozen plasma should be given. There comes a critical point in the bleeding when the clotting factors become depleted and whatever name is applied to the syndrome, at that moment, the patient's clotting time is extended to infinity. Though this could not always be clearly documented, this point usually comes after six to eight transfusions of red blood cells, whether stored blood or autotransfusion is used. When this point is recognized, the better alternative to further frustration may well be to pack the site and resort to replacement of red blood cells and clotting factors in a carefully monitored intensive care environment. Presently in this country the use of component blood products is becoming standard practice, and the luxury of fresh whole blood is becoming a thing of the past. Fresh frozen plasma, cryoprecipitate, and platelets, as indicated, should be used early in the care of these patients, and continued through the postoperative period. The liver is the site of production of these factors, and presumably has been functionally impaired by the injury. This coagulopathy is amplified by hypothermia, which occurs commonly after massive transfusion of cold blood and blood products. Maintenance of normothermia is essential in these patients, and the use of efficient, high performance, simple blood warmers is sorely needed. Such a device has recently been described[35]; however, its clinical efficacy remains unproven.

Our experience with injuries involving the retrohepatic vena cava previously described is similar to that of Walt.[18] Only when these injuries can be anticipated and suspected, and the patients' clinical condition allows time for deliberate planning, do the shunting and inflow bypass procedures stand a real chance of being successful. At present, the best approach to juxtahepatic vascular injuries appears to be that of Pachter et al.,[36] who advocate external cooling of the liver, use of large doses of steroids, occlusion of hepatic inflow, and a direct approach to the injury through the liver, if necessary, using the *finger fracture* technique and point ligation of bleeding vessels. Until better preoperative recognition is achieved, such as through the efforts of Federle et al.[37] using computed tomography, immediately available in the resuscitation area, or until technical advances in surgery occur making it possible to isolate the liver easily from its vasculature so that necessary repairs can be made in a dry operating field, mortality rates with these injuries will continue to be high.

There have been impressive advances in the care of these critically injured patients especially in the area of intensive management, in control of sepsis, pulmonary care, nutrition, anesthesia, and technical instrumentation in monitoring. In trauma centers that care for civil trauma, the concept of a dedicated liver team alluded to by Spencer[38] should be seriously considered. Other considerations might be the use of external pump bypass set up in advance for suspected severe liver injury or the routine insertion of an intracaval shunt easily placed through a groin vein before the abdomen is opened.[39] Advances must continue to be made in safety standards for the roads and highways. There must be insistence by traumatologists that our government pass legislation to require air bags or equivalent restraints. The people who should be wearing seat belts just do not wear them!

Summary

This is a study of 323 patients from a major trauma center of liver injury caused exclusively by blunt trauma. The entire spectrum of known technical interventions to control liver hemorrhage were utilized by the full-time staff of traumatologists. A mortality rate of 58.4% on 101 patients with marked hemorrhage from the severely injured liver is noted. This is in the range noted in other studies.[13] Overall, the mortality rate for the 323 patients was 31% and for those who died from liver injury if they survived the celiotomy (17 patients) the mortality rate was 5.26%. Conservatism in the management of the more seriously injured patients is supported by the statistics collected during the study. Liberal replacement of blood clotting factors is advocated. Earlier consideration of packing to the liver might reduce the formidable mortality rates in those patients with serious injury. Dedicated liver trauma teams in institutions, where feasible, is encouraged.

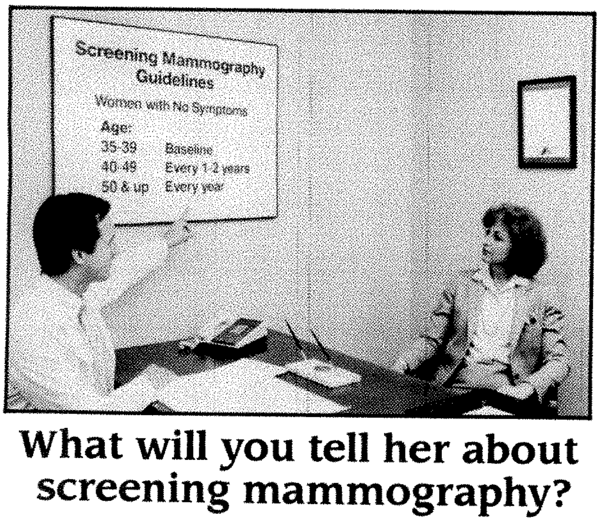
THE BILLINGS CLINIC

Certified Cardiopulmonary Perfusionist

Progressive medical center in the Northwest area is seeking a certified Cardiovascular Perfusionist. Qualifications: Applicant must be certified or eligible for certification as a Perfusionist; licensure as a registered nurse is helpful but not required; demonstrated ability to work effectively with cardiovascular team. Salary commensurate with experience, excellent benefits.

Forward resume to:

Personnel Manager
The Billings Clinic
P.O. Box 35100
Billings, MT 59107-5100.



What will you tell her about screening mammography?

Many of your patients will hear about screening mammography through a program launched by the American Cancer Society and the American College of Radiology, and they may come to you with questions. What will you tell them?

We hope you'll encourage them to have a screening mammogram, because that, along with your regular breast examinations and their monthly self examinations, offers the best chance of early detection of breast cancer, a disease which will strike one woman in 10.

If you have questions about breast cancer detection for asymptomatic women, please contact us.

5th Annual International

Breast Cancer Seminar

Presented in Cooperation with the American Cancer Society

MIAMI

March 24 - 26, 1988

HOTEL INTER•CONTINENTAL MIAMI

Join 14 leading specialists from all over the world at this post graduate seminar. They will be discussing the latest developments in the diagnosis and treatment of all forms of breast disease.

Participants Include:

JOHN BOSTWICK, III, M.D.
Emory Clinic, Section of Plastic and Reconstructive Surgery, Atlanta, Georgia
DIANA BRINKLEY, M.D.
Consultant in Radiotherapy and Oncology, London
AMAN U. BUZDAR, M.D.
Professor of Medicine, Medical Breast Service, University of Texas, M.D. Anderson Hospital, Houston, Texas
ROBERT CALLAHAN, Ph.D.
Chief, Oncogenetics Section, Laboratory of Tumor Immunology and Biology, National Cancer Institute
GARY M. CLARK, M.D.
University of Texas, Health and Science Center, Department of Medicine/Oncology, San Antonio, Texas
ISAIAH J. FIDLER, D.V.M., Ph.D.
Professor and Chairman, Department of Cell Biology, M.D. Anderson Hospital and Tumor Institute, Houston, Texas
BERNARD FISHER, M.D.
Distinguished Service Professor, Department of Surgery, University of Pittsburgh, School of Medicine
ROBERT L. GOODMAN, M.D.
Professor and Chairman, Department of Radiation Therapy, University of Pennsylvania School of Medicine
FRANK E. GUMP, M.D.
Chief, Breast Service, Columbia-Presbyterian Medical Center, New York
DANIEL KOPANS, M.D.
Director of Breast Imaging, Harvard Medical School
LANCE LIOTTA, M.D.
Pathology Department, National Cancer Institute
SUSAN M. LOVE, M.D.
Director of Breast Clinic, Beth Israel Hospital, Boston
BERNARD PIERQUIN, M.D.
Chief, Dept. Cancerologie, Henri Mondor Hospital, France
LASZLO TABAR, M.D.
Mammography Dept., Central Hospital, Falun, Sweden

Approved for 17 hours of Category I Credit.

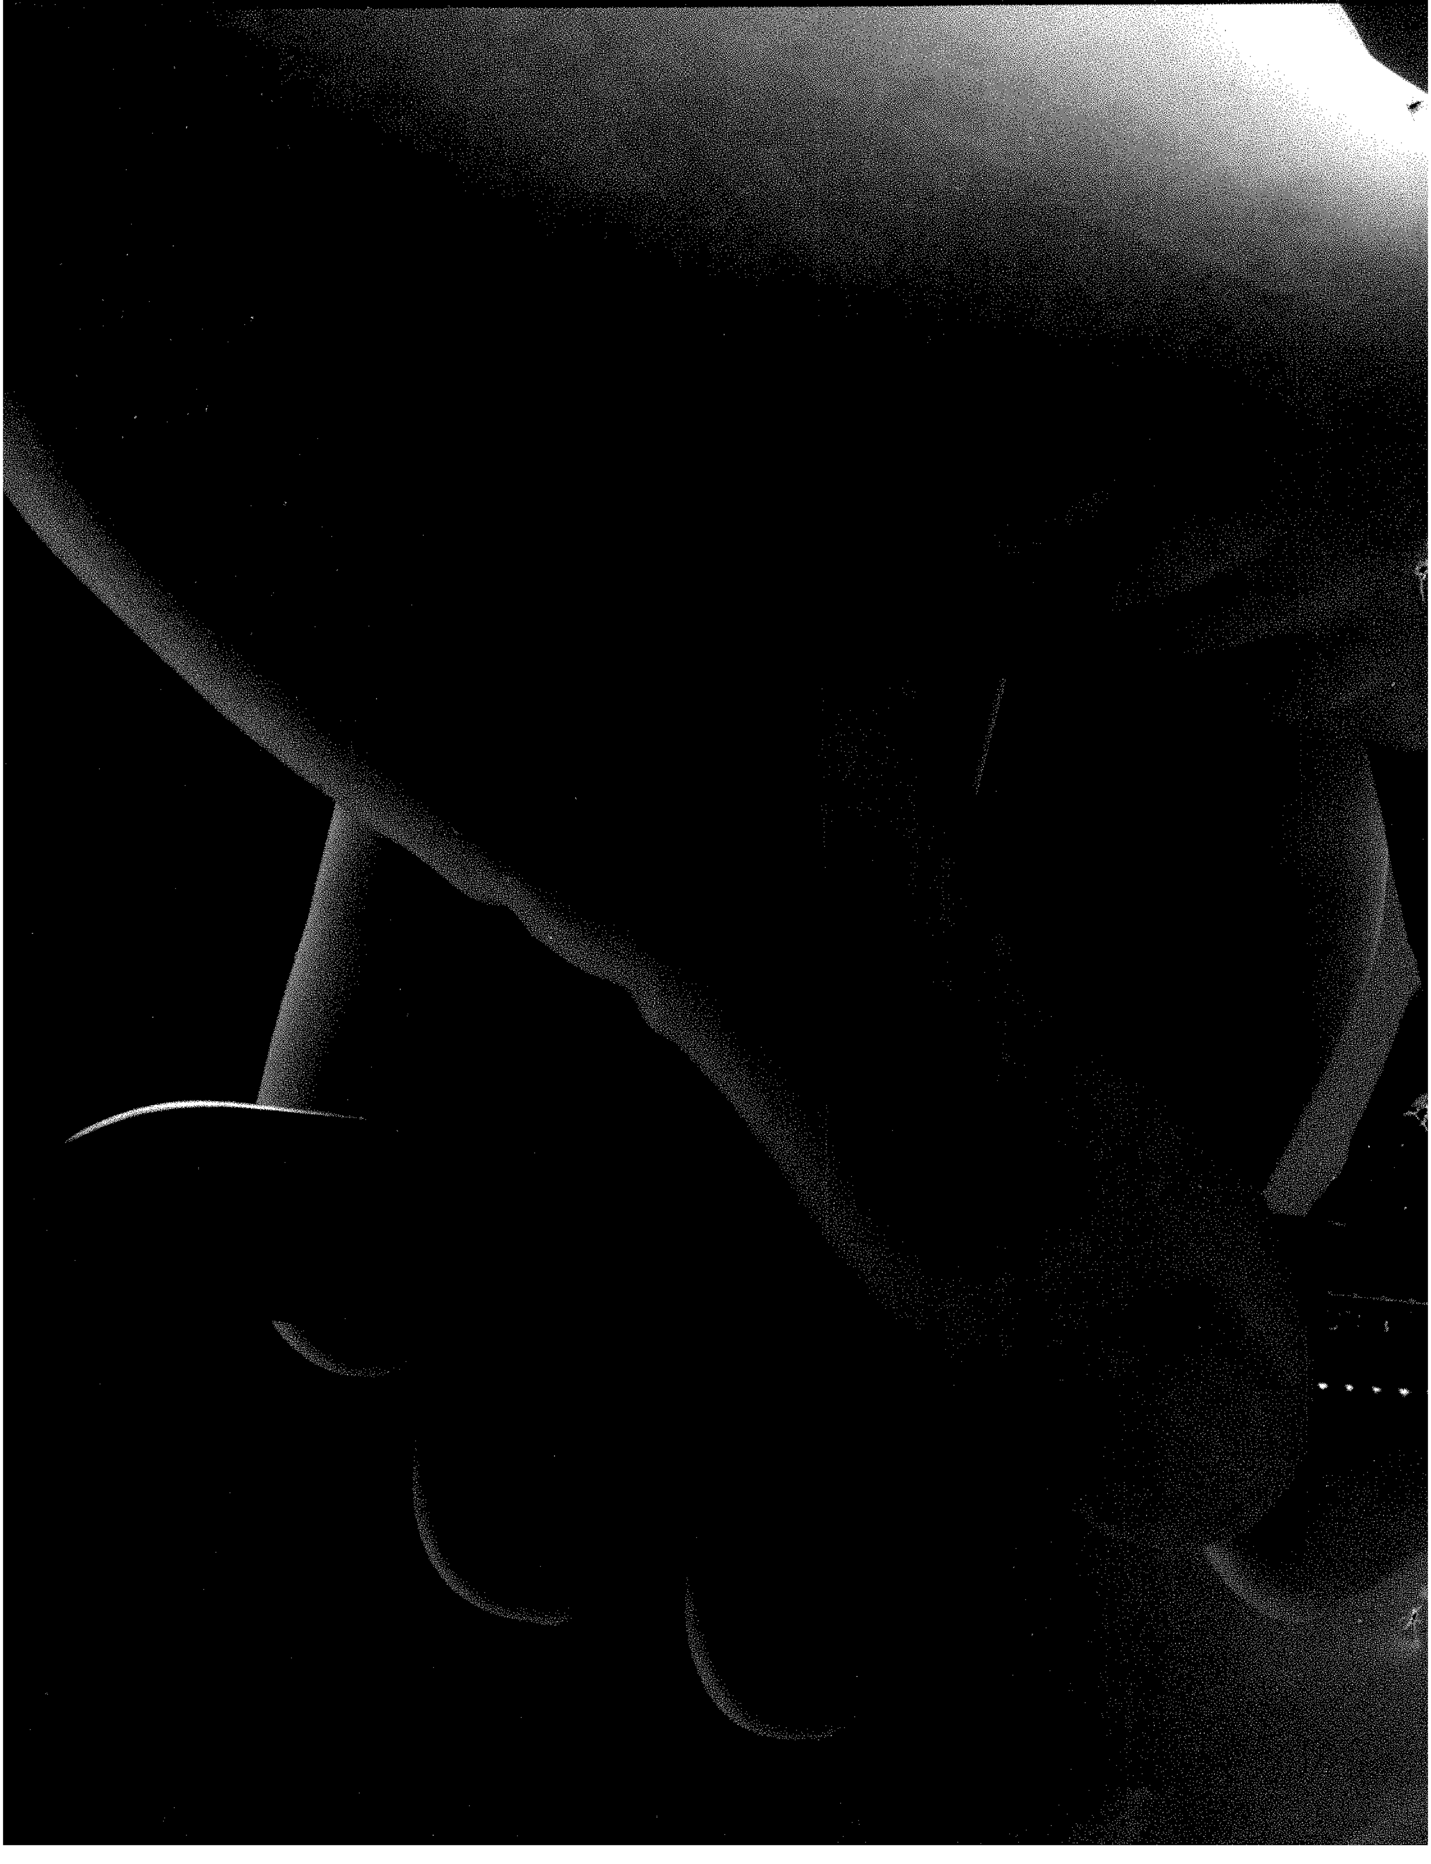
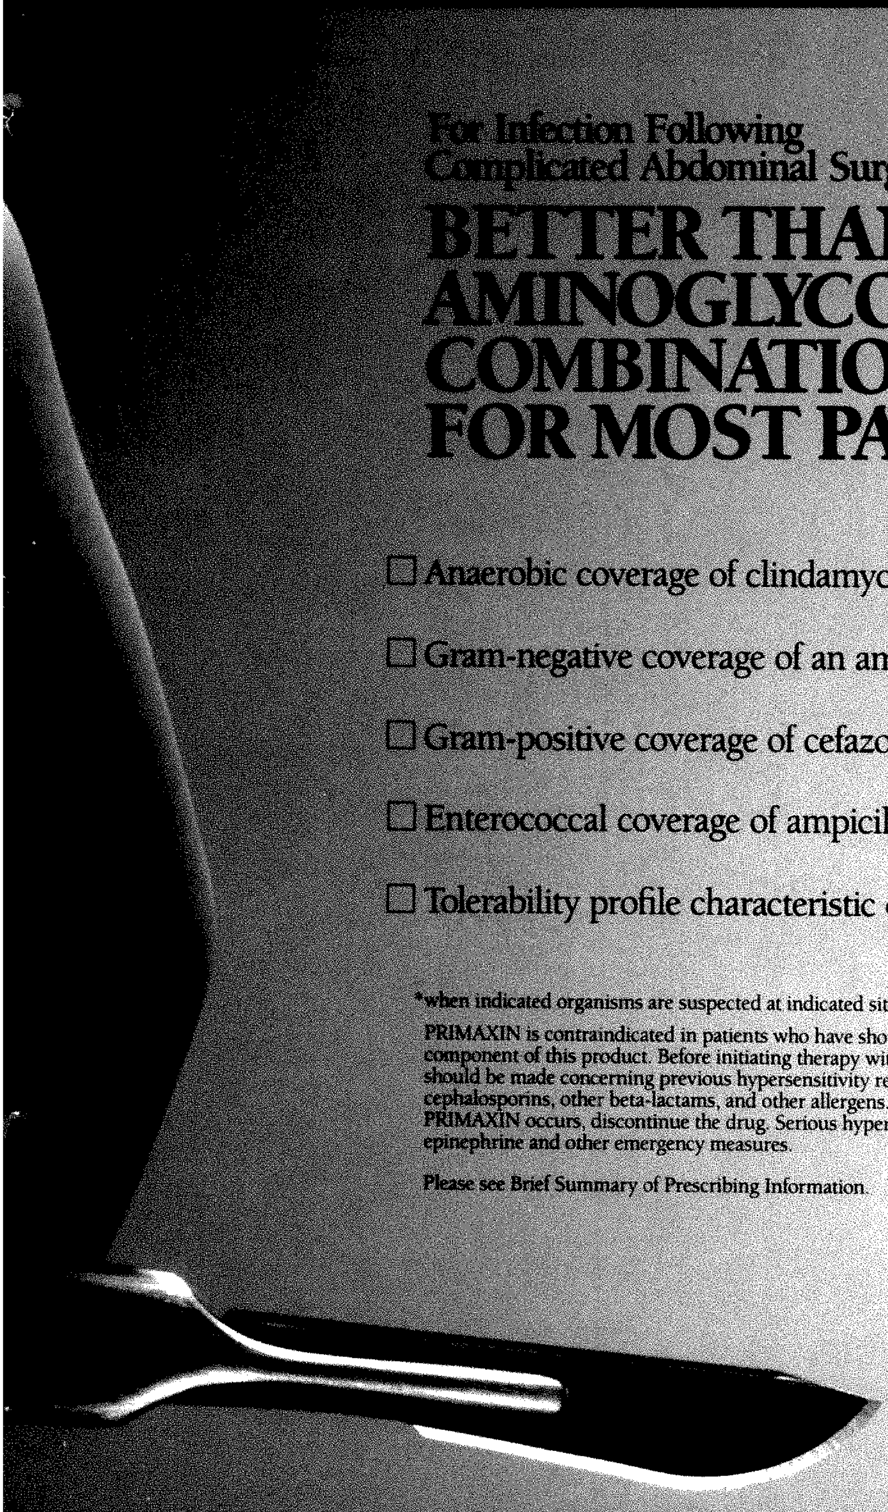
DEFINING A NEW STANDA



D* FOR EMPIRIC THERAPY



For Infection Following Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

☐ Anaerobic coverage of clindamycin or metronidazole plus

☐ Gram-negative coverage of an aminoglycoside plus

☐ Gram-positive coverage of cefazolin plus

☐ Enterococcal coverage of ampicillin plus

☐ Tolerability profile characteristic of beta-lactam antibiotics

*when indicated organisms are suspected at indicated sites

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

Please see Brief Summary of Prescribing Information.

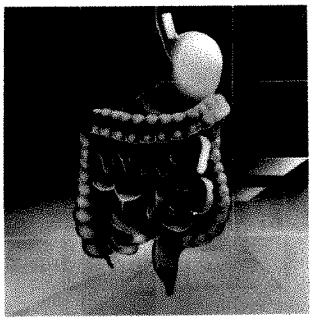
DEFINING A NEW STANDARD* FOR EMPIRIC THERAPY

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium|MSD)



Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN,' CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of ≤ 5 mL/min/1.73 m^2 should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

Pregnancy—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in non-pregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Renal*—oliguria/anuria, polyuria; *Skin*—erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage®† vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

Surgical *Versus* Endoscopic Management of Common Bile Duct Stones

B. M. MILLER, M.D., R. A. KOZAREK, M.D., J. A. RYAN, JR., M.D., T. J. BALL, M.D., and L. WILLIAM TRAVERSO, M.D.

From the Departments of Surgery and Gastroenterology, Virginia Mason Medical Center, Seattle, Washington

The charts of all patients with common bile duct (CBD) stones admitted to Virginia Mason Medical Center between January 1, 1981 and July 31, 1986 were reviewed to define current methods of management and results of operative *versus* endoscopic therapy. Two hundred thirty-seven patients with CBD stones were treated. One hundred thirty patients had intact gallbladders. Of these patients, 76 (59%) underwent cholecystectomy and common bile duct exploration (CBDE) while 54 (41%) underwent endoscopic papillotomy (EP) only. Of the 107 patients admitted with recurrent stones after cholecystectomy, all but five were treated with EP. The overall mortality rate was 3.0%. Complications, success, and death rates were all similar for CBDE and EP, but the complications of EP were often serious and directly related to the procedure (GI hemorrhage, 6; duodenal perforation, 5; biliary sepsis, 4; pancreatitis, 1). Patients undergoing EP required significantly shorter hospitalization than those undergoing CBDE. Multivariate analysis showed that age greater than 70 years, technical failure, and complications increased the risk of death, regardless of procedure performed. Twenty-one per cent of those undergoing EP with gallbladders intact eventually required cholecystectomy. The conclusion is that the results of EP and CBDE are similar, and the use of EP has not reduced the mortality rates of this disease.

CARL LANGENBUCH performed the first cholecystectomy in 1882,[1] and for the first 90 years thereafter, operation formed the mainstay of therapy for benign biliary tract disease. In the early 1970s, however, techniques were developed in the fields of radiology and gastroenterology that would provide alternative therapeutic options and radically change management of biliary lithiasis. For example, in 1973 Burhenne reported fluoroscopically guided basket retrieval of common bile duct (CBD) stones via the T tube tract.[2] In 1974 Claasen and Demling from Germany[3] and Kawai from Japan[4] independently described endoscopic papillotomy (EP).

EP is performed using a lateral viewing duodenoscope. Vater's papilla is cannulated first with a diagnostic catheter, and a cholangiogram confirms the presence of stones and defines their size and location. The diagnostic catheter is then replaced with a papillotome, a diathermy wire attached to a teflon catheter. The papilla is cannulated to a variable depth, and the diathermy wire is oriented away from the pancreatic sphincter. An electrical current is passed down the wire, creating a 1- to 1½-cm incision, depending on the length of the sphincter and the size of the stones. The stones may be immediately retrieved with a Dormia basket or they may be allowed to pass spontaneously. A nasobiliary drainage catheter may be placed to prevent cholangitis if complete stone evacuation has not been accomplished.[5,6]

Initially, EP was reserved for frail patients at high risk for operation with retained or recurrent CBD stones. Early reports documented mortality rates of 1–2%[4] and major morbidity rates (pancreatitis, bleeding, and duodenal perforation) of 7–10%.[7-9] These figures compared favorably with historical surgical controls from the 1950s and 1960s when the mortality rate after operative common bile duct exploration (CBDE) was at least 5%.[10,11] Considering this comparison and the greater patient satisfaction, EP rapidly gained wide acceptance and its applications broadened. In centers where skilled endoscopists practice, EP has become the procedure of choice for recurrent stones after cholecystectomy.[12,13] In addition, it is being used with increasing frequency in

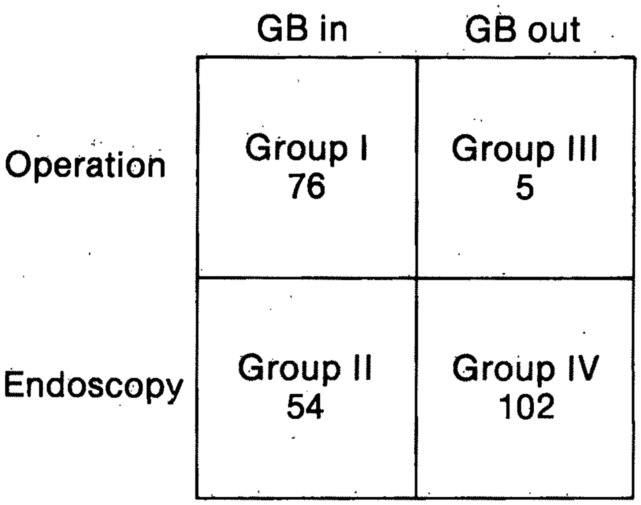

FIG. 1. Division of patients into four groups based on the presence of a gallbladder at the time of admission and initial procedure performed. Number of patients in each group is given in parentheses.

patients with intact gallbladders and common duct stones.[14]

The following report was undertaken to define the impact of EP on management of choledocholithiasis at a multispecialty referral center. Specifically, we wished to analyze how patients are initially treated, what the current results of EP and CBDE are, and whether EP has reduced the overall mortality rate of patients with CBD stones.

Patients and Methods

The Virginia Mason Medical Center (VMMC) is a multispecialty clinic located in Seattle, WA, which draws referrals from the Pacific Northwest and Alaska.

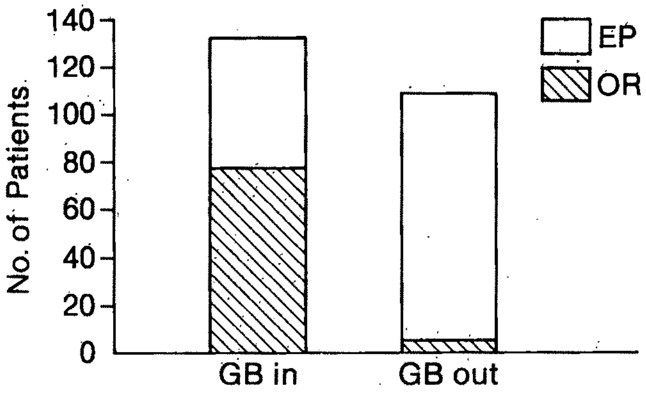

FIG. 2. Type of procedure initially performed in patients with and without gallbladders.

A computer list was generated of all patients admitted between January 1, 1981 and July 31, 1986 with the diagnosis of choledocholithiasis. The charts of these patients were screened, and only those with CBD stones documented unequivocally by retrieval or cholangiogram were included in this analysis. Two hundred thirty seven patients had common bile duct stones during this study period.

The charts of these patients were reviewed for the following data: previous cholecystectomy, procedures performed, age, year of admission, comorbid illness, acute presentation, complications, death, and technical success of procedure. In addition, patients who underwent EP without prior cholecystectomy were interviewed by telephone regarding recurrence of stones and need for subsequent procedures.

The entire population (N = 237) was divided into four groups based on two factors: the presence of a gallbladder at the time of admission and the initial procedure attempted at VMMC (Fig. 1). Patients in group I (N = 76) had intact gallbladders and underwent cholecystectomy and CBDE with or without a biliary enteric drainage procedure. Group II patients (N = 54) also had intact gallbladders, but underwent EP only as the initial procedure. Group III patients (N = 5) had undergone prior cholecystectomy and were treated with CBDE, while those in group IV (N = 102) with prior cholecystectomy underwent EP.

Statistical Analysis

The BMDP statistical package program was used for statistical analyses.[15]

Continuous variables were analyzed by analysis of variance (ANOVA).[16] A one-way ANOVA was performed to test the equality of means between two groups. This program also tests the equality of variances between the two groups (Levene's test for equal variances, a robust test computed on the absolute values of the deviations from the means).[17] Two additional one-way ANOVA statistics are also computed. Neither of these assumes the equality of variances in each group, which are: (1) the Welch statistic and (2) the Brown-Forsythe statistic.[18] These tests were used when the variances were found to be unequal between the two groups.

For multivariate analysis, Cox's logistic regression method was employed. In this model:

$$[V = \log P/1 - P = A + B_1X_1 + B_2X_2 + B_3X_3 \cdots]$$

where A represents the log odds of disease risk for a person with a standard (X = 0) set of regression vari-

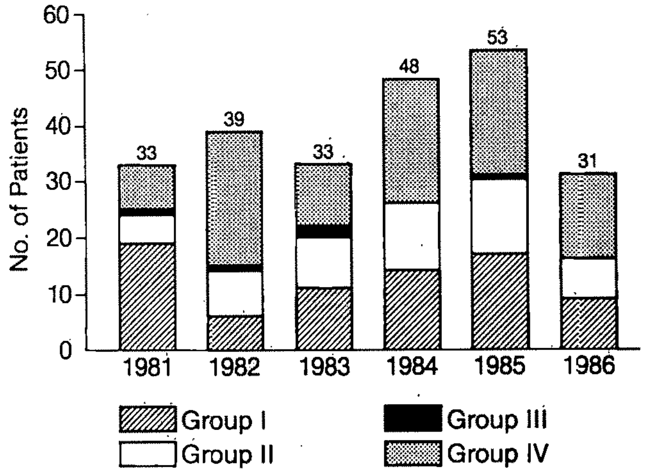

FIG. 3. Total number of patients admitted each year with CBD stones, and their distribution into the four treatment groups.

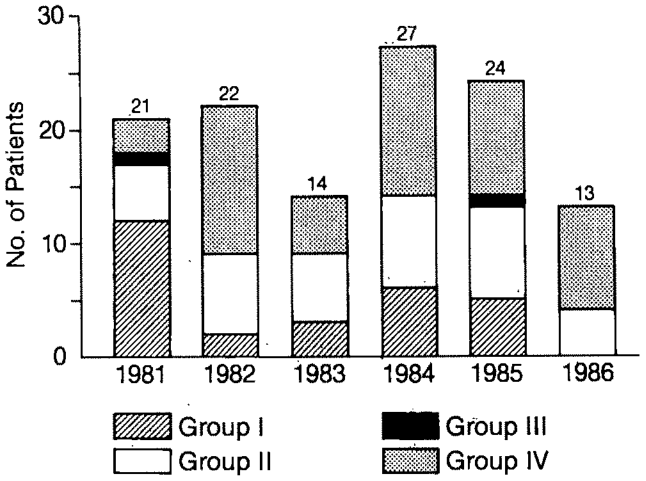

FIG. 4. The total number of patients over 70 years admitted each year with CBD stones is depicted. The patients are divided into treatment groups.

ables, while exp (B_k) is the fraction by which this risk is increased (or decreased) for every unit change in X_k.[19]

Results

Of the 237 patients, 130 had intact gallbladders (groups I and II) and 107 had retained or recurrent stones after cholecystectomy (groups III and IV). Of those with intact gallbladders, 76 underwent cholecystectomy and CBDE (59%) while 54 underwent EP (41%). Of the 107 patients who had previously undergone cholecystectomy, all but five had EP attempted as the initial procedure (Fig. 2). The number of patients with CBD stones increased during the last 3 years of the study (Fig. 3). The number of patients undergoing EP with gallbladders intact also rose during each successive year of the study, but this was in proportion to the overall increase in patients with CBD stones. The only year in which the majority of patients underwent operation was 1981 (20 out of 33). Each year thereafter, the large majority of patients underwent papillotomy.

The transition from CBDE to EP became even more apparent when examining only those patients over 70 years of age. Although the number of patients admitted per year remained stable in this age group, the number admitted for CBDE dropped sharply after 1981 (Fig. 4). For example, 12 of the 28 patients in group I who were over 70 years of age underwent operation in 1981; the remaining 16 operations were distributed fairly evenly over the next four years. The number of patients in group II over 70 years of age increased slightly over the study period, so that during the 5½ years of this review, the majority of patients over 70 with intact gallbladders underwent EP as opposed to CBDE (38 *vs.* 28). Thirty-five of the 38 patients who underwent EP in group II were referred directly to gastroenterologists and had no surgical consultation prior to the procedure.

Table 1 characterizes the four groups according to age, number of comorbid illnesses, and percentage of patients presenting with acute biliary tract disease. For each patient, the number of comorbid illnesses was determined, and the number listed in Table 1 represents the arithmetic mean for each group. The number listed under acute illness represents the percentage of each group that presented with either acute cholecystitis, cholangitis, or pancreatitis. The mean age of patients in group I was significantly less than that of groups II and IV ($p < 0.05$). There were no differences, however, in the mean number of comorbid illnesses per group or the fraction that presented acutely ill.

Again, examining only patients in groups I and II over 70 years of age (Table 2), we found that those undergoing CBDE were still younger than those undergoing EP ($p < 0.05$). These groups were also similar with regard to

TABLE 1. *Group Characteristics*

Group	Age (yr) (Mean)	Age (yr) (Range)	No. of Comorbid Illnesses (Mean)	Acutely Ill (%)
I	58 ± 2*	19–88	1.2 ± 0.1	40
II	75 ± 2	25–104	1.7 ± 0.1	35
III	68 ± 6	50–84	1.0 ± 0.8	20
IV	68 ± 1	30–97	1.6 ± 0.1	23

* Group I *vs.* II and I *vs.* IV, $p < 0.05$.

TABLE 2. *Group Characteristics: Age >70 Years with Intact Gallbladder*

Group	Age (yr) (Mean)	Age (yr) (Range)	No. of Comorbid Illnesses (Mean)	Acutely Ill (%)
I	75 ± 1*	70–89	1.5 ± 0.2	36
II	84 ± 1	70–104	1.6 ± 0.2	42

* Group I *vs.* II, $p < 0.05$.

acute and chronic illnesses. Thus, EP was the preferred method of treating elderly patients with intact gallbladders, regardless of underlying health.

Length of hospitalization was greater for patients treated with CBDE than for those treated with EP ($p < 0.05$). Patients in group I were hospitalized 10.3 ± 0.6 days compared to 6.4 ± 0.8 for group II; group III patients spent 16.0 ± 4.8 days in the hospital compared to 6.0 ± 0.6 for group IV.

Technical success of the procedure was defined as clearance of all stones from the bile ducts. Retained stones constituted failure for the operative groups (groups I and III). Multiple endoscopic procedures were commonly necessary to achieve clearance in groups II and IV. Such cases were still considered technically successful if clearance was ultimately attained without need for operation. Table 3 lists the success rates for all groups. All five patients with retained stones after CBDE underwent percutaneous basket retrieval via the T tube tract without complication. Of the 23 patients who had unsuccessful attempts at EP, 18 underwent subsequent CBDE.

Table 4 depicts the complication rates for each group, and Table 5 lists the complications according to procedure (EP *vs.* CBDE). While the overall group complication rates did not differ significantly, the nature of the complications seemed more serious in patients undergoing EP. Sixteen of the 22 complications occurring in groups II and IV were directly a result of EP. There were six episodes of gastrointestinal (GI) hemorrhage (2 to 12 U), five duodenal perforations, four instances of biliary sepsis, and one case of pancreatitis. Seven of these 16 complications resulted in a need for operation (GI bleed, 3; duodenal perforation, 2; biliary sepsis, 2), which represented 4.7% of the total number of patients who underwent EP. In contrast to the EP complications, five of the 13 CBDE complications were directly a result of the procedure. Two of these complications (hemorrhage and pancreatitis) necessitated reoperation, representing 2.5% of all patients undergoing CBDE.

TABLE 3. *Technical Success Rate*

Group	N	Failures	Success Rate (%)	Subsequent Procedures (N)
I (CBDE)	76	4	95	Basket extraction (4)
II (EP)	54	6	89	CBDE (3)
III (CBDE)	5	1	80	Basket extraction (1)
IV (EP)	102	17	85	CBDE (15)

TABLE 4. *Complication Rate*

Group (N)	Complications (%)
I (76)	11 (14)
II (54)	5 (9)
III (5)	2 (40)
IV (102)	17 (16)

Seven of the 237 admissions for choledocholithiasis ended in hospital death. These seven patients are characterized in Table 6. The youngest patient who died was 70 years old. Each patient's group assignment reflects the initial procedure performed at VMMC. Only one patient had CBDE as the initial procedure. Four of the seven patients eventually required both EP and CBDE. One patient had undergone cholecystectomy and CBDE elsewhere and was transferred ten days postoperatively for endoscopic retrieval of a retained stone. Three patients underwent EP, then subsequently required operation for continued symptoms, technical failure, or complications. Myocardial infarction and sepsis were the most frequent causes of death.

The overall mortality rate was 3.0%, 5.8% for patients 70 years or older, and 0% for patients less than 70 (Table 7). Mortality rates were similar for all groups.

Cox's logistic regression method indicated that three factors increased the risk of death: presence of complications, age of 70 years or older, and technical failure. The following factors did not independently increase the risk of mortality: number of comorbid illnesses, type of procedure initially attempted, and presentation with acute biliary tract conditions.

Follow-up data were obtained for 34 of 48 patients (72%) who had successful EP with intact gallbladders. The mean length of follow-up was 28 months. Seven of these patients (21%) underwent subsequent cholecystectomy for either acute cholecystitis or chronic continued symptoms. One patient underwent laparotomy elsewhere and was found to have chronic pancreatitis. Her gallbladder was not removed. One patient had two separate episodes of CBD stones during the study period and was treated twice with EP. Another patient had her first EP in 1980 before the study period and had her second EP in 1984 for another episode of stones.

7	87	IV	CBDE, EP	−	MI

Discussion

In examining the recent management of choledocholithiasis at VMMC, we found that the overwhelming majority of patients with CBD stones after cholecystectomy were treated with EP. This was not surprising, in view of VMMC's regional reputation for skilled endoscopy and the current trend in both Europe and the United States to treat recurrent stones in this manner.[8,12,13] During the past 5½ years, however, 41% of all patients with gallbladders intact, and 58% of patients over 70 years of age with gallbladders intact, were initially treated with EP. While the patients who underwent EP were significantly older than those undergoing CBDE, they were similar with regard to both chronic comorbidity and the fraction that presented acutely ill. Thus, at our institution, EP has become the preferred method of treating elderly patients with CBD stones and gallbladders intact, regardless of underlying health. This unexpected preference reflects the current thinking of general physicians and gastroenterologists since 92% of these elderly patients underwent EP without prior surgical consultation.

Can this radical shift in management be justified on the basis of improved results? The technical success rates of EP and CBDE were similar, and compared favorably with those reported by other institutions.[14,20,22] While the overall complication rates were also similar, we found that the actual complications of EP were more frequently life-threatening and were most often a direct result of the procedure (GI hemorrhage, duodenal perforation, biliary sepsis). Nearly half of these EP-related complications necessitated a subsequent, often urgent operation. The overall complication rate of 14% associated with EP may seem high when compared to other reports. Most studies on EP have reported only the procedure-related complications,[8,9,14,23] thus lowering the published rates and making comparison to surgical series somewhat imbalanced. In addition, one of these reports[14] noted a complication rate of 13% when cases were reviewed by an independent observer, as in the current study. Mortality rates of all groups were also similar and may seem high for EP and low for CBDE. This may be explained by two factors. First, four of the seven patients who died required both EP and CBDE, making it difficult to attribute the death to one procedure or the other. Second, the patients who underwent EP were older than those who underwent CBDE, making comparison between the groups less valid. Several series have recently been published that examine the results of CBDE before EP was widely utilized, and thus before it exerted any such selection bias. Pitt et al.[24] reported no deaths in 47 patients undergoing cholecystectomy and CBDE; Broughan et al.[13] reported a 0.8% mortality rate for operation on patients with recurrent stones only; McSherry and Glenn[25] reviewing 30 years experience, reported a mortality rate of 3.2% for all patients undergoing CBDE. Others document similar mortality rates.[26] Our mortality rate of 3.0% is within this range. These data suggest that CBDE can be performed with morbidity and mortality rates at least equal to those currently observed for EP, and that the widespread use of EP at our institution has not reduced the overall mortality of CBD stones.

Recognizing the limitations of retrospective studies, we subjected our data to multivariate analysis, and

TABLE 7. *30-Day Mortality Rates*

Group	Deaths (%)	Deaths (%) Patients >70 Years
I	1 (1.3)	1 (3.6)
II	2 (3.7)	2 (5.3)
III	0	0
IV	4 (3.9)	4 (7.5)
Total	3.0	5.8

found that, indeed, type of procedure performed was not an important determinant of mortality rate. Rather, age greater than 70 years, technical failure, and presence of complications significantly increased the risk of death. Although four of the seven patients who died eventually required both EP and CBDE, the need for a second procedure did not independently increase risk when adjusted for technical failure. Numerous studies have documented age as a risk factor for benign biliary tract procedures.[10,24,25,27] This has generally been attributed to the greater proportion of elderly patients who require emergent procedures and to concurrent chronic illness.[26,28] Our data, however, do not support these notions. We did not find that acute cholecystitis, pancreatitis, or cholangitis negatively affected survival. In addition, the risk of mortality did not increase in proportion to the number of comorbid conditions, and age remained a significant risk factor even when adjusted for chronic disease. Thus, the elderly patient remains fragile with regard to biliary tract procedures, regardless of underlying health. Whichever procedure is chosen should be performed successfully and without complication.

Of the patients undergoing EP with intact gallbladders, 21% required subsequent cholecystectomy. The cholecystectomy rates reported by other institutions range from 8.6%–28%.[14,23,29,30] Siegel et al.[30] recently reported that 109 of 1272 patients (9%) who underwent EP with gallbladders intact developed acute cholecystitis within 10 days of the procedure. The majority of these patients responded to medical management, but 25 required operation. Eight of the patients who required emergent operation died. This suggests that acute cholecystitis should also be considered a frequent and potentially fatal complication of EP in patients with intact gallbladders. Endoscopists have reasoned that EP spares the need for CBDE even if cholecystectomy becomes necessary, and thus should reduce the morbidity and mortality rates of operation. Neoptolemos et al.[31] recently tested this theory with a prospective study. Patients were randomly assigned to undergo either cholecystectomy with CBDE or EP followed by cholecystectomy 3 days later. The complication and death rates were nearly doubled for the latter group, although the study was halted before the differences became statistically significant. This implies that the risks for the two procedures (EP and cholecystectomy) are additive and that the risk of EP in these patients was at least as great as the risk of CBDE.

In 1980 McSherry and Glenn stated that "the mortality rates of secondary choledochotomy and endoscopic papillotomy are comparable and that . . . acceptance of [EP] on the basis of less mortality and morbidity in comparison to surgical therapy is unjustified."[25] Our data confirm this opinion. We believe, however, that EP should remain the procedure of choice for CBD stones after cholecystectomy. While use of EP is not justified on the basis of improved results, it does permit less in-hospital time, which implies greater cost-effectiveness and patient satisfaction. The role of EP alone as the initial therapy for patients with intact gallbladders, however, is not yet clearly established. Although cholecystectomy may be avoided in 75–80% of these patients, this benefit must be weighed against the excessive mortality risk that accompanies complicated unsuccessful procedures ending in emergent operation. Studies suggest that certain subsets of patients with intact gallbladders might benefit from early EP, such as those with cholangitis[32] or pancreatitis.[33] These groups remain to be defined by controlled, prospective studies.

Reoperation for Congenital Choledochal Cyst

TAKUJI TODANI, M.D., YASUHIRO WATANABE, M.D., AKIRA TOKI, M.D., NAOTO URUSHIHARA, M.D.,
and YASUHISA SATO, M.D.

Kagawa Medical School, Kagawa, Japan

A reoperation after excisional procedure was carried out in seven cases due to early or late postoperative complications. Of the 12 patients with early complications, four underwent relaparotomy due to anastomotic leakage and bleeding. Late complications were seen in nine patients with recurrent cholangitis caused by an anastomotic stricture, and three patients with intrahepatic involvement required a reoperation several years after the initial surgery. Recurrent cholangitis after biliary reconstruction mainly occurs due to an anastomotic stricture of the hepaticoenterostomy. There was no significant difference in the results between hepaticoduodenostomy and hepaticojejunostomy over a long follow-up period. A wide anastomotic stoma that permits free drainage of bile into the intestine is imperative to the prevention of cholangitis, and can be created by an incision extending along the lateral wall of both the hepatic ducts with a hepaticoenterostomy at the hilum. This procedure is obviously necessary in all patients with or without intrahepatic involvement. Carcinoma of the intrahepatic ducts and the retained distal choledochus have rarely developed in patients undergoing cyst excision followed by biliary reconstruction. Complete excision of the whole extrahepatic bile duct could prevent carcinoma arising in the distal choledochus, although it could not prevent carcinoma arising from the intrahepatic ducts. However, patients with carcinoma of the intrahepatic duct were reported to have had symptoms of biliary stricture for a long time since the cyst excision. Bile stagnation in the intrahepatic ducts is possibly responsible for the development of carcinoma. A wide anastomosis resulting in free drainage of bile appears to be essential to the prevention of carcinoma arising in the intrahepatic ducts after cyst excision.

SURGICAL TREATMENT of choledochal cyst has changed recently. Enteric drainage procedures, cystoduodenostomy, and cystojejunostomy have been abandoned due to high morbidity rates and the potential danger of carcinoma development in the cyst wall; cyst excision followed by biliary reconstruction is gaining recognition as the treatment of choice.[1-4] Moreover, excision interrupts an anomalous pancreatobiliary ductal union that is commonly observed in choledochal cysts and results in hazardous effects to the biliary epithelium due to refluxing of pancreatic juice.[5] The cyst excision, however, has led to several early and late postoperative complications. Of 92 patients who underwent various procedures at the Okayama University Hospital and the Hospital of Kagawa Medical School, 23 patients who underwent reoperation are reviewed in this article.

Clinical Data

Between 1960 to 1986, 92 patients with choledochal cyst underwent various procedures without operative mortality at our clinics. Cysts were classified by our classification[4]: type Ia, cystic dilatation (21 patients), type Ic, diffuse dilatation (18), type III, choledochocele (1), and type IV-A, intrahepatic involvement (52) patients. Eight patients died of carcinoma arising in the cyst soon after surgery.[6] Five of these patients had primary, and three had secondary carcinoma, which developed several years after enteric drainage. In the remaining 84 patients without carcinoma, primary excision of the cyst was performed in 60, and secondary excision converted from various drainages was done in 13 patients. A total of 73 patients finally underwent excisional procedures with biliary reconstruction: hepaticoduodenostomy in 51, hepaticojejunostomy Roux-en-Y in 20, pancreatoduodenectomy in 1, and excision of choledochocele in 1. The 11 patients who were treated prior to 1967 still have enteric drainage and have been lost to follow-up study. Of the 73 with cyst excision, seven patients underwent a relaparotomy due to several postoperative

complications. In total, 23 patients of reoperation for choledochal cyst were analyzed.

TABLE 1. *Reoperation of Choledochal Cyst*

	Reoperation			
Former Operation	Ex and H-D	Ex and H-J	Palliative Operation	Total
Cholecystostomy	4	3	—	7
Choledochostomy	—	1	—	1
Cystoduodenostomy	3	1	2	6
Cystojejunostomy Roux-en-Y	—	1	1	2
Cyst excision	5	2	—	7
Total	12	8	3	23

Palliative operation was carried out in three patients with carcinoma.

Ex = cyst excision, H-D = hepaticoduodenostomy, H-J = hepaticojejunostomy Roux-en-Y.

Results

Reoperation was performed in 23 patients, 8 of whom had external drainage, 8 of whom had enteric drainages (including 3 who developed carcinoma), and 7 of whom underwent excisional procedures (Table 1). The reoperation rate in the 84 patients without carcinoma was 14.3% (12/84), excluding the 8 patients with external drainage.

Reoperation in Cases of External Drainage

All eight patients with external drainage underwent secondary excisional procedures with favorable results. Seven of these patients underwent cholecystostomy primarily due to severe cholangitis in 4, acute pancreatitis in 1, and bile peritonitis in 2. The remaining patient underwent cholecystectomy with T tube choledochostomy, and hepaticojejunostomy Roux-en-Y at the hepatic hilum with end-to-end anastomosis was performed secondarily after removal of the whole extrahepatic bile duct because of an anomalous pancreatobiliary ductal union that was identified with tube-cholangiograms.

Reoperation in Cases of Enteric Drainage

Of the 19 patients with enteric drainage, 5 patients underwent secondary excision of the cyst due to recurrent cholangitis with abdominal pain and high fever occurring several years after surgery and 3 patients ended up with palliative operation due to carcinoma that developed in the retained cyst (Table 2). The remaining 11 patients with enteric drainage were experienced prior to 1967 and have been lost to follow-up study.

Reoperation in Cases of Excisional Procedure

An excisional procedure was performed in 73 patients, of whom 21 patients had postoperative complications: early in 12 and late in nine. A reoperation, however, was carried out in only seven patients.

The early complications generally could be managed conservatively with favorable results (Table 3). Only four patients underwent a reoperation due to anastomotic leakage and postoperative bleeding. Of two patients with anastomotic leakage, one underwent a conversion from a hepaticocholedochostomy to a hepaticojejunostomy Roux-en-Y on the 11th postoperative day, and the other underwent a relaparotomy due to unsuitable drainage of bile caused by kinking of the silastic drain near the anastomotic site. Postoperative bleeding developed in two patients. One had massive bleeding from the dissected layers around the pancreatic head on the day of the operation, and several pursestring sutures around the bleeding site were effective. The other patient had bleeding from the site of hepaticoduodenostomy, which was converted into a hepaticojejunostomy Roux-en-Y after closing of the duodenal stoma.

Late complications occurred due to recurrent ascending cholangitis caused by anastomotic stricture. Several attacks of cholangitis with abdominal pain and high

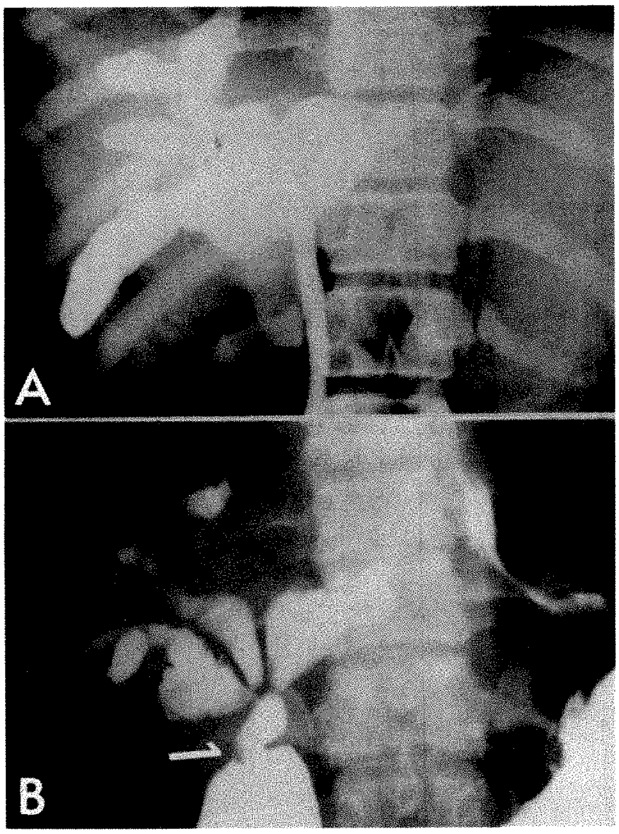
fever were observed in nine patients (12.3%). The cholangitis usually responded to antibiotics and resulted in no demonstrable hepatic dysfunction subsequently. Of these nine patients, five patients underwent hepaticoduodenostomy and four underwent hepaticojejunostomy Roux-en-Y. Seven patients had a type IV-A cyst (intrahepatic involvement). Only three patients with intrahepatic involvement, however, required a reoperation several years after excisional procedures.



FIGS. 1A and B. Case 1. *A*. Operative cholangiogram at the age of 11 shows dilatation of the intrahepatic ducts near the hilum. *B*. Cholangiogram at the age of 18 shows cloverlike strictures on the confluence of both the hepatic ducts. The arrow indicates the anastomosis of the hepaticoduodenostomy below the hilum.

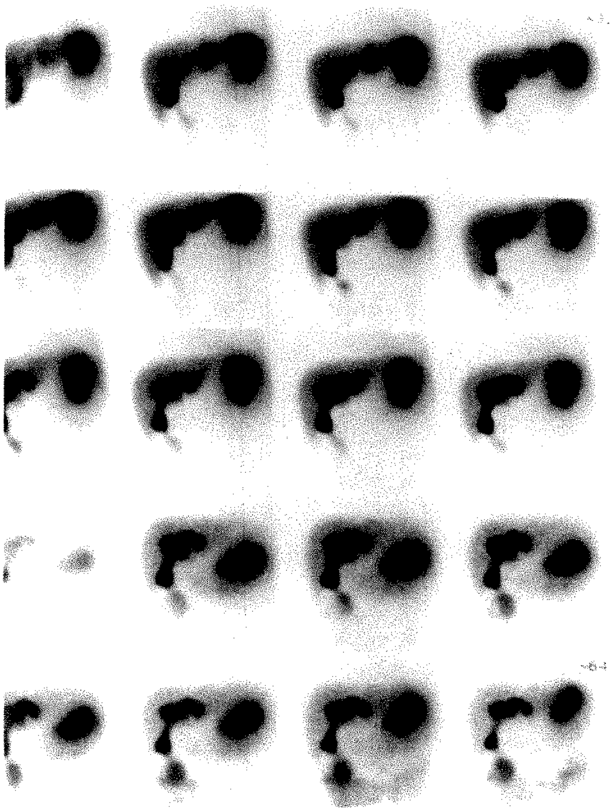


FIG. 2. Case 2. Scintigrams delineate well the intrahepatic ducts near the hilum and the jejunal interposition even at 60 minutes after injection of ^{99m}Tc HIDA, and suggest strictures of both the hepaticojejunal and jejunojejunal anastomoses.

Case Reports

Case 1

The patient had undergone cyst excision with hepaticoduodenostomy below the hepatic hilum at the age of 11 years.[7] She had occasionally complained of abdominal pain and fever beginning 2 years after surgery. At the age of 18, strictures of the confluence of the bilateral hepatic ducts were revealed by endoscopy and barium study (Fig. 1). The hepaticoduodenostomy was converted to a hepaticojejunostomy Roux-en-Y at the hilum with end-to-end anastomosis after plasty of both the hepatic ducts. She is now 29 years old without any symptoms.

Case 2

A 2-year-old boy underwent a cyst excision elsewhere followed by hepaticojejunostomy with jejunal interposition (22 cm in length) performed distal to the hilum with end-to-side anastomosis. However, he complained of intermittent abdominal pain and fever several months after surgery. At the age of 6, scintigraphy using ^{99m}Tc HIDA suggested an anastomotic stricture, which was confirmed with operative cholangiograms (Fig. 2). A relaparotomy revealed intrahepatic biliary calculi and slight stricture of the jejunojejunal anastomosis with dilatation of the jejunal blind pouch (Fig. 3). The hepaticojejunostomy was changed to a hepaticoduodenostomy at the hilum. He has been free of symptoms for 12 months since the second surgery.

Case 3

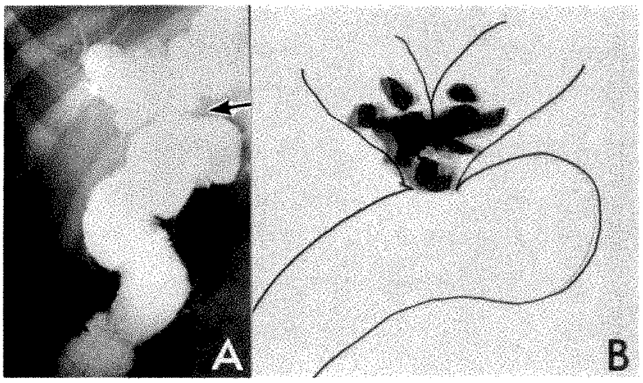
A 5-year-old girl underwent an excisional procedure with hepaticoduodenostomy below the hilum due to diffuse dilatation of the extrahepatic bile duct with bilateral intrahepatic involvement (Fig. 4). Severe abdominal pain with high fever occasionally developed since the age of 11 years. At the age of 12, a gastrointestinal tract examination with barium showed no demonstrable biliary tree, suggesting an anastomotic stricture. Endoscopy and ^{99m}Tc HIDA scintigraphy revealed a stricture of the anastomotic stoma with highly dilated intrahepatic ducts containing numerous biliary stones. After left hepatectomy and complete removal of biliary calculi in the right lobe, the hepaticoduodenostomy was released, and a wide anastomosis between the right intrahepatic duct and Roux-en-Y jejunum was performed. She has remained well for 4 months since surgery.

Discussion

External drainage is usually carried out on patients in poor general condition, resulting from septicemia due to cholangitis, acute pancreatitis, biliary perforation, or hepatic dysfunction with jaundice, and excisional procedure can be performed without any difficulty within a few months after the surgery. If an enteric drainage was performed when the patient is in poor condition, the patient might hesitate to undergo a definitive operation due to transitory improvement of complaints. Cholecystostomy is recommended as a drainage procedure because of its simplicity and usefulness as a guide for dissection of the cyst.

Recurrent cholangitis, anastomotic stricture with jaundice, biliary calculi, and carcinoma in the cyst tend to occur after enteric drainage, and correction surgery is frequently necessary (Table 4).[3,6,8–14] The risk of developing carcinoma in the retained cyst appears to be 50%,[9] and the mean age at detection of carcinoma is 35 years of age, 15 years younger than that of primary carcinoma. The prognosis is very dismal, and all patients with enteric drainage die soon after the detection of carcinoma.[6] The development of carcinoma is possibly caused by regurgitation of pancreatic juice into the choledochus through an anomalous pancreatobiliary union that is usually observed in choledochal cyst. Enteric drainage leaves a malunion and cannot interrupt refluxing of pancreatic juice. Therefore, it should be abandoned and converted early to excisional procedure, even if the patient has no complaints. A secondary excision is easier than previously thought. Blunt dissection of the inner layer of the shrunken cyst can avoid injury to the hepatic artery and portal vein by leaving the outer layer intact.[2,15]

An excisional procedure with biliary reconstruction is the treatment of choice in terms of preventing malignant complications and interrupting a malunion. Morbidity and mortality rates with cyst excision are seldom seen due to recent advances in operative techniques and postoperative management.[1,2,10,12,16] However, early and



FIGS. 3A and B. Case 2. *A*. Operative cholangiogram at the age of 6 shows a stenosis of the hepaticojejunostomy (arrow) with dilatation of the intrahepatic ducts and jejunal blind pouch. *B*. Biliary calculi are seen in the hepatic ducts just above the anastomosis.

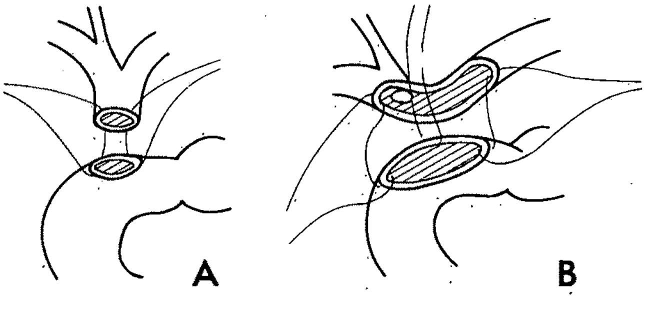
late complications of excisional procedures have occasionally been reported.[9,11,12,14]

Early complications include an anastomotic leakage, bleeding from the dissected outer layer or gastrointestinal tracts, acute pancreatitis, pancreatic fistula, and intestinal obstruction. Minor leakage can be managed effectively by long-term drainage. However, hepaticocholedochostomy, so-called anatomical reconstruction, is inappropriate for choledochal cyst, even if leakage does not occur[14,17] due to leaving a pancreatobiliary malunion that causes the refluxing of pancreatic juice. Bleeding from the dissected layer of the cyst can be prevented with electrocoagulation or pursestring sutures. Gastrointestinal bleeding due to a peptic ulcer might occur in patients with hepaticojejunostomy,[18] and could be treated with H2 blockers. Acute pancreatitis and pancreatic fistula[12] may be caused by dissecting the terminal bile duct, which is connected with the pancreatic duct in the pancreatic head. These problems can usually be managed conservatively. Intestinal obstruction would be expected to develop more often in hepaticojejunostomy Roux-en-Y patients than in hepaticoduodenostomy patients because of the necessity to manipulate the abdominal cavity below the transverse mesocolon in the former. Hepaticoduodenostomy at the hilum, however, is prone to cause a transient duodenal obstruction due to kinking of the duodenum caused by lifting it up to the hepatic hilum after extended kocherization. Most of these obstructions tend to be managed successfully by nasogastric drainage with fasting for several days. A duodenal obstruction due to compression by the jejunal limb after a hepaticojejunostomy Roux-en-Y has been reported to be an unusual complication that requires correction surgery.[19]



FIGS. 5A and B. *A.* Hepaticoduodenostomy below the hilum. *B.* Hepaticoduodenostomy at the hilum with a wide stoma created by an incision along the lateral wall of the hepatic ducts.

Existence of late complications is very important in evaluation of a surgical procedure. Cholangitis, biliary calculi, and carcinoma have been occasionally observed in long-term follow-up studies after excisional procedures, and have become the object of reoperations.[10]

Recurrent cholangitis with severe abdominal pain, high fever, and biliary calculi after biliary reconstruction is a serious complication. It mainly occurs due to biliary stasis caused by an anastomotic stricture of hepaticoenterostomy, particularly in patients with intrahepatic involvement. Biliary stasis also develops from a stricture of the jejunojejunal anastomosis in the Roux-en-Y jejunum or the jejunoduodenal anastomosis in hepaticoduodenostomy with jejunal interposition, and from compression of a jejunal limb with the preduodenal portal vein.[19] No significant difference was found in the results between hepaticoduodenostomy and hepaticojejunostomy Roux-en-Y over a long follow-up period. A wide anastomotic stoma, which permits free drainage of bile juice into the intestine, may be imperative to the prevention of cholangitis.[2,15] A wide anastomosis cannot be produced in an anastomosis between the common hepatic duct and the intestine because the common hepatic duct is relatively small and commonly had a denuded mucosa with marked fibrosis that resulted in a stenosis. A wide stoma can be created by an incision extending along the lateral wall of both the transected hepatic ducts, and then hepaticoenterostomy is performed at the hilum (Fig. 5). This procedure is obviously necessary in all patients with or without intrahepatic involvement. In the Roux-en-Y procedure, an end-to-side anastomosis with blind pouch formation, which might be performed to adapt the size of the common hepatic duct, should not be carried out. An end-to-end anastomosis with plasty of both the hepatic ducts to fit with the jejunal stoma is recommended. Moreover, anastomosis with cyst remnants leaving after excision to get a sufficiently large stoma is also probably unsuitable because of leaving the mucosa prone to malignant change.

Carcinoma of the intrahepatic ducts and the distal choledochus developed in 12 patients who underwent an apparently insufficient cyst excision followed by biliary reconstruction (Table 5).[20-23] Complete excision of the extrahepatic bile duct from the hilum to the pancreatobiliary junction could prevent carcinoma arising in the distal choledochus retained after insufficient excision,[6,12,23] while it could not prevent carcinoma arising from the intrahepatic ducts. However, the four reported

cases of carcinoma of the intrahepatic duct had symptoms of biliary stricture for a long time from the time the cyst was excised until the carcinoma was detected.[12,21,22] Long-lasting bile stagnation in the intrahepatic ducts is possibly responsible for the development of carcinoma. A wide anastomotic stoma yielding free drainage of bile after cyst excision is probably essential to the prevention of carcinoma arising in the intrahepatic biliary tree.

Risk Factors in Relation to Postoperative Complications in Patients Undergoing Esophagectomy or Gastrectomy for Cancer

MASAHARU NISHI, M.D., YOSHIFUMI HIRAMATSU, M.D., KOSHIRO HIOKI, M.D., YOSHIFUMI KOJIMA, M.D., TOSHIAKI SANADA, M.D., HIDEHARU YAMANAKA, M.D., and MASAKATSU YAMAMOTO, M.D.

From the Department of Surgery, Kansai Medical University, Osaka, Japan

To clarify the risk factors contributing to postoperative complications in the elderly patients (over 70 years) undergoing esophagectomy and/or gastrectomy, 364 patients with primary cancer seen were evaluated. As a result, some characteristic patterns of stress response in the elderly could be detected as follows: the disorders of the vital organs were more important indices for the development of postoperative complications rather than age, and a reduction in the maximum response of the stress hormones to surgical procedures in aged patients was noted; moreover, the functional variability of target organ in the aged group was confirmed. Studies on the hormonal response to surgery suggest that the restriction of fluid replacement is advisable until the third postoperative day, maintaining the host on the dry side, to prevent cardiopulmonary complications. As the nutritional status in the patients with esophageal and gastric cancer goes from bad to worse with the advancing clinical stages, adequate perioperative nutrition is imperative to prevent complications such as anastomotic leakage, wound dehiscence, and/or infections. For the treatment of anastomotic leaks after esophagectomy and esophagogastrectomy, more than 45 kcal/kg/d must be provided, and the serum albumin level must be restored to 3.5 g/dL in order to achieve spontaneous healing of small anastomotic leakages.

DESPITE IMPROVEMENTS in preoperative evaluation, operative techniques, and postoperative care, esophageal resection and reconstruction through a combined thoracoabdominal procedure for the patients with esophageal and/or proximal gastric cancer still remains a formidable operation in patients whose nutritional and pulmonary status have been compromised by impaired swallowing.[1]

Since esophagectomy or esophagogastrectomy is associated with a high rate of complications, mainly pulmonary complications and anastomotic leakage, a preoperative assessment of cardiopulmonary function and nutritional status is thought to be mandatory.[2] Besides, esophagectomy and/or esophagogastrectomy with thoracotomy elicit a maximal the stress response especially in elderly patients with cancer of the esophagus and/or proximal stomach.

Since the functional reserve of various organs is decreased in elderly patients, the selection of the most suitable surgical procedure and the assessment of each patient's tolerance for surgical stress are difficult to determine. In recent years, aggressive nutritional support and proper nutritional assessment during the perioperative period have become essential in achieving a satisfactory recovery because the operations for esophageal and gastric cancer have become more radical and more extensive.[3,4] It is also imperative to clarify the relationship between anastomotic leaks and the nutritional status in these cancer patients.

The present study was designed to analyze the significant risk factors that could contribute to postoperative complications following esophagectomy or esophagogastrectomy, and to investigate the characteristic pattern of stress response to surgery for primary cancer of the esophagus and/or proximal stomach in patients over 70 years old.

Materials and Methods

During the 6-year period from 1980 through 1985, there were 364 patients with primary cancers of the esophagus and stomach who underwent esophagectomy, esophagogastrectomy, and/or partial gastrectomy

TABLE 1. *Comparison Between Aged and Control Group of Patients with Esophageal or Esophagocardial Carcinoma with Respect to Preoperative Organ Impairment*

	Aged Group (N = 89)	Control Group (N = 275)
Impaired cardial function*	44 (49%)	62 (22%)
Impaired pulmonary function*	36 (40%)	32 (12%)
Impaired liver function	6 (7%)	21 (8%)
Impaired renal function*	13 (15%)	9 (3%)
Impaired nutritional status	31 (35%)	74 (27%)
Others	15 (17%)	20 (7%)
Total	145 (163%)	218 (79%)

* Statistically significant by chi-square test ($p < 0.005$).

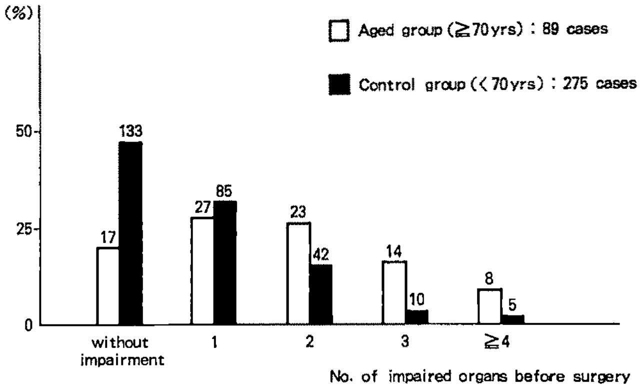

FIG. 1. Comparison between aged and control patients with respect to impaired organ function seen before surgery.

in our clinic. Of these 364 patients, the last 22 were analyzed with regard to their stress hormone responses and functional changes in the major vital organs in response to surgical stress. There were 19 men and 3 women, ranging in age from 43 to 78 years old, with an average age of 63.4 years. The 22 patients were separated by age into two groups consisting of equal numbers of patients. Eleven of them were over 70 years old and the other 11 patients were under 70 years old.

All of the patients with cancer of esophagus and/or cardia underwent either total or partial resection of the esophagus, through a right or left thoracoabdominal approach, with reconstruction using a stomach tube or a portion of the colon as a substitute placed via the posterior mediastinal route or retrosternal route.

The levels of renin (R), aldosterone (Ald), antidiuretic hormone (ADH), epinephrine (E), and norepinephrine (NE) were measured at 14 specified times during the perioperative period (within 10 days after surgery). Blood catecholamines were measured by the HPLC-THI method,[5] and the remainder were measured by radioimmunoassay methods.[6-8]

For perioperative nutritional assessments, 34 patients with esophageal cancer at different stages were analyzed. Changes in the actual body weight as a percentage of the ideal body weight (%IBW) were calculated. As an index of body habitus, tricep skinfold thickness (TSF) and arm muscle circumference (AMC) were measured by the method of Blackburn et al.[9] Sixty-two patients admitted for cholecystectomy were also investigated as controls. They were otherwise healthy and had normal liver function tests on admission to the hospital. All of the other clinical data were obtained by routine methods in our clinical laboratory. The diagnoses of anastomotic leakage and pulmonary complications were confirmed on clinical data and radiologic findings. Pulmonary complications were documented by location (right or left) and type (atelectasis, pulmonary edema, bronchopneumonia, and other pulmonary abnormalities).

Results

Of 364 patients with primary esophageal and/or gastric cancer, 89 (24%) were over 70 years old. With respect to risk factors, of the 89 patients in the elderly group, 72 (81%) showed some impairment of vital organs preoperatively, whereas of 275 patients under 70 years old, only 142 (52%) had such a preoperative impairment. There were significant differences between the older group and the control group with regard to the preoperative impairment of cardiac, pulmonary, and renal function ($p < 0.005$) (Table 1). In addition, the

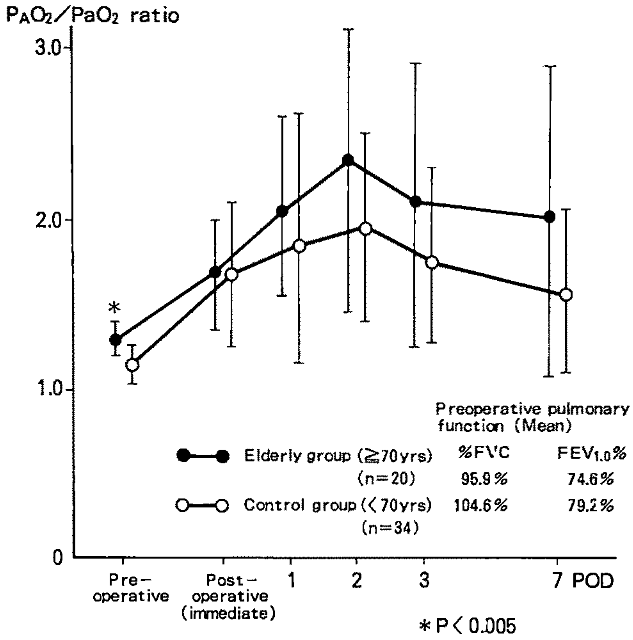

FIG. 2. Comparison between aged and control groups with respect to the perioperative change of oxygenation in patients undergoing esophagectomy or esophagogastrectomy for cancer. Results are given as mean ± SD. *Significant difference between two groups by Student's t-test ($p < 0.005$).

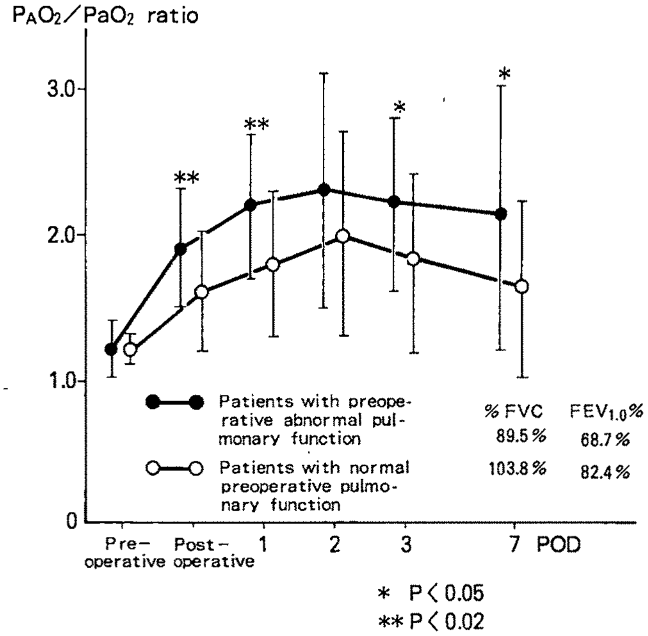

FIG. 3. Comparison of sequential measurement of oxygenation in patients with preoperative impaired pulmonary function and those with normal pulmonary function. Results are given as mean ± SD. *Statistically significant between two groups ($p < 0.05$); **$p < 0.02$.

patients over 70 years old had much more multiorgan impairment than did the control group; of 89 elderly patients, 45 (55%) showed two or more organ impairment, whereas only 21% of the control group had multiorgan impairment (Fig. 1).

With respect to the relationship between the preoperative impairment of organ function and the incidence of postoperative complications, there were no significant correlations between the two groups; however, when postoperative complications did develop in the older patients, they often progressed to multiorgan failure and death.

There were significantly lower values with respect to the nutritional assessment such as %IBW, total protein (TP), albumin (Alb), hemoglobin, and cholinesterase in the elderly patients with esophageal and/or gastric cancer, as compared to those with gallstones, whereas there were no significant differences in the measurements of organ function such as insulinogenic index ($\Delta IRI/\Delta BS$), prothrombin time, $FEV_{1.0\%}$, $\dot{V}_{25}$, GFR, and $PSP_{15'}$ between two groups.

Figure 2 illustrates the comparison between the aged and the control groups with respect to postoperative oxygenation (PAO_2/PaO_2 ratio) in patients undergoing esophagectomy and/or esophagogastrectomy for cancer. Although there were significant differences in the preoperative PAO_2/PaO_2 ratio between the elderly and the control groups, no significant difference was found after surgery. However, patients with a preoperative impairment of respiratory function showed significantly lower postoperative PAO_2/PaO_2 ratios than did the patients with no impairment (Fig. 3). These results suggest that the preoperative degree of organ impairment, rather than age, is predictive of postoperative difficulty and should be used in assessing preoperative risk.

The secretion of stress hormones in response to surgery was evaluated separately for each operative proce-

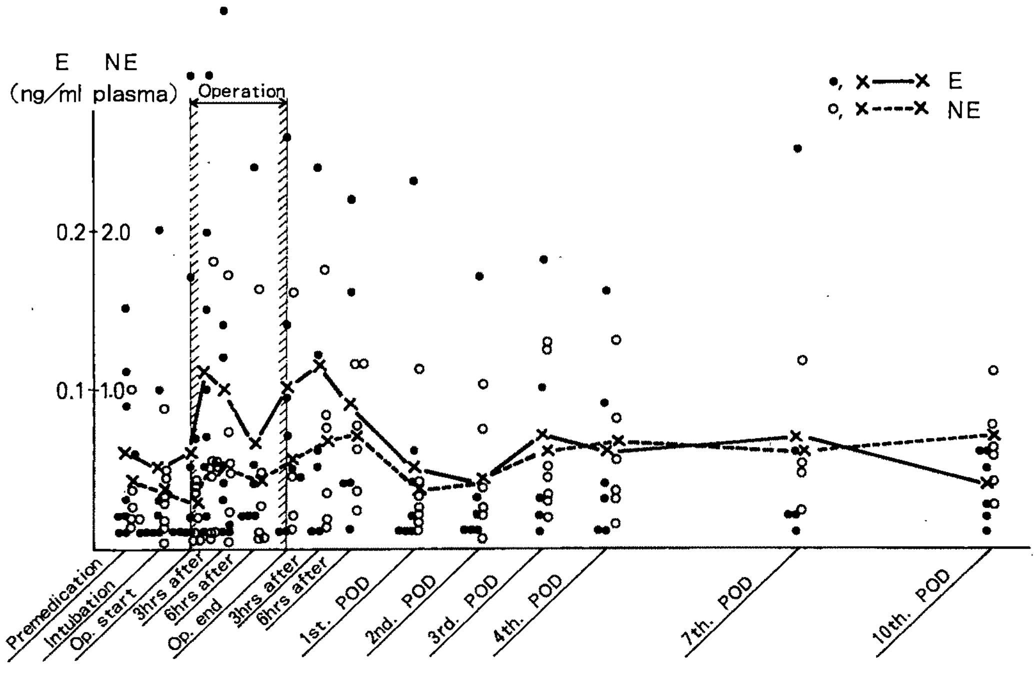

FIG. 4. Perioperative changes in the plasma catecholamine levels in patients undergoing esophagectomy for cancer.

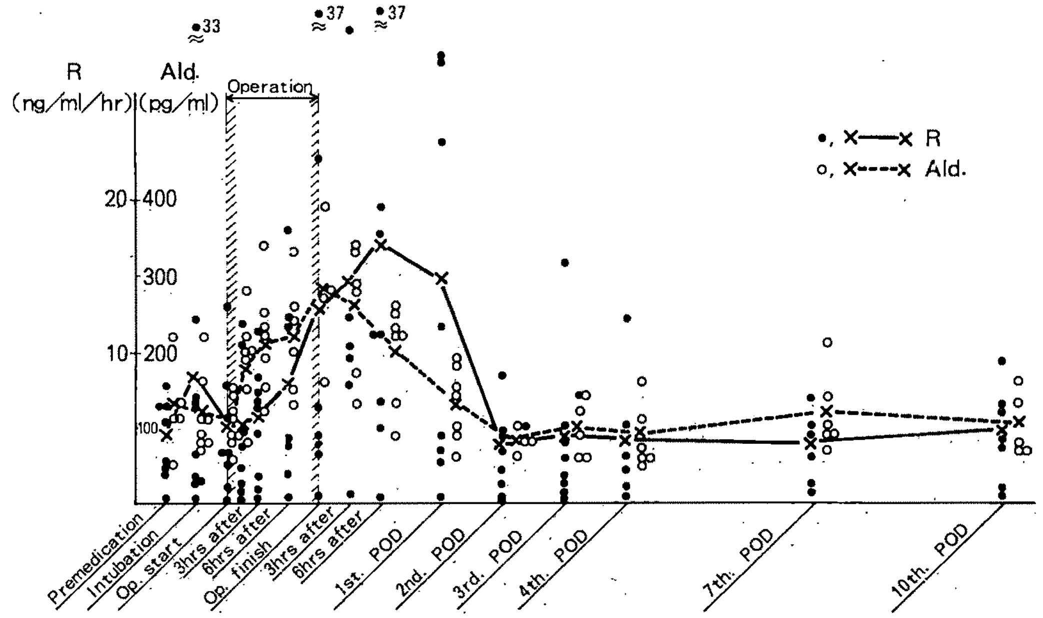

FIG. 5. Perioperative changes in the plasma renin and aldosterone levels in patients undergoing esophagectomy for cancer.

dure: esophagectomy through a combined right thoracic and abdominal approach, total gastrectomy with pancreatectomy and splenectomy, and partial gastrectomy. The plasma E level was maximally elevated at 3 hours after the initial skin incision, whereas the plasma NE reached peak levels at 6 hours after the completion of surgery (Fig. 4). There was no correlation between the plasma E levels at 3 hours after incision and the magnitude of surgical stress as indicated by the type or duration of the operative procedure, or the intraoperative blood loss. Nor was there any significant correlation between the plasma NE levels at 6 hours after the completion of surgery and the above three factors. These results indicate that the response of the plasma catecholamines to surgical stress definitely does not reflect the magnitude of stress; this finding contradicts a previous report indicating that the plasma level of catecholamines is proportional to the magnitude of surgical stress.[10]

Figure 5 shows the perioperative changes in the levels of plasma R and Ald in patients undergoing esophagectomy. The peak levels for both the plasma R and Ald were within 6 hours after the termination of surgery and returned to the preoperative levels on the second postoperative day except in one patient with chylothorax. The perioperative changes of the urinary Na/K ratio are illustrated in Figure 6, in which the lowest value was seen on the first POD, followed by a gradual return to the preoperative values.

Figure 7 illustrates the comparison between the elderly and the control groups with respect to the maxi-

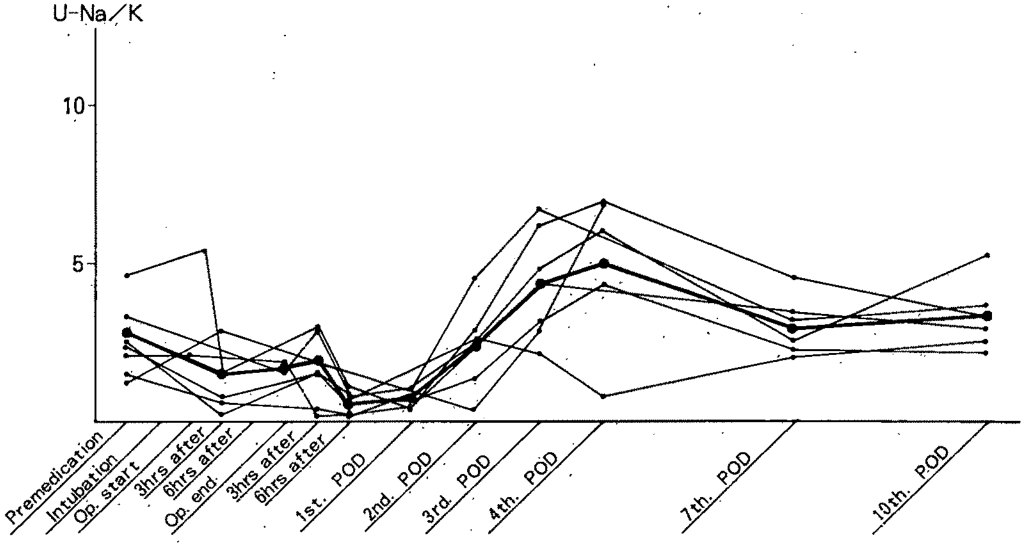

FIG. 6. Perioperative changes in the urinary Na/K ratio in patients undergoing esophagectomy for cancer.

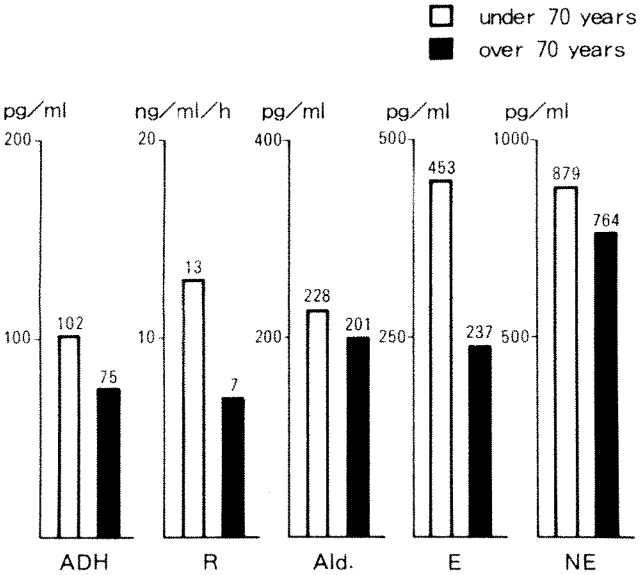

FIG. 7. Comparison between aged and control patients with respect to the peak levels of various stress hormones.

mum response (peak levels) of five stress hormones (R, Ald, ADH, E, and NE) within 24 hours after surgery in patients undergoing esophagectomy and/or gastrectomy. It was evident that the maximum responses of stress hormones in the patients over 70 were definitely decreased as compared with those of the patients under 70 years; the 50% decrease in plasma R activity and E level was particularly conspicuous.

To clarify the influence of the decreased hormonal response in the aged patients on the function of the target organ, the following studies were carried out. The plasma aldosterone levels of all patients and those of patients under 70 years showed a significant correlation with the urinary Na/K ratio, the regression lines for each group being $Y = 3.74 - 8.51X$ ($r = -0.416$, $p < 0.001$) and $Y = 4.51 - 11.4X$ ($r = -0.426$, $p < 0.001$), respectively (Fig. 8). However, there was no correlation between the plasma levels of aldosterone and the urinary Na/K ratio in the patients over 70. It seems reasonable to speculate from these results that not only does the maximum response to surgical stress become dull and the secretion of hormones get delayed, but also each target organ shows suboptimal function because of a diminished response to the appropriate stress hormone. This may be due to a diminution of hormone receptors in the target organ and/or primary end-organ impairment. These results account for the high incidence of postoperative cardiopulmonary complications in the aged.

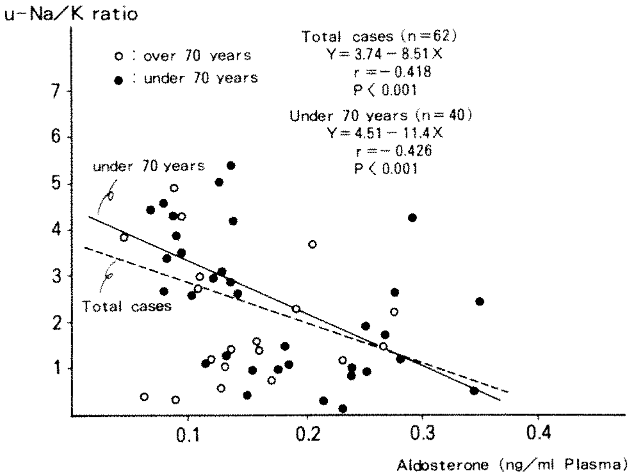

FIG. 8. Correlation between the plasma aldosterone concentration and urinary Na/K ratio during and after surgery.

Figure 9 illustrates the significant decreases in multiple nutritional parameters varying according to the stage of cancer of the esophagus, using patients with gallstones as control. An especially remarkable decrease was seen in the patients with recurrent cancer. As shown in Figure 10, an extremely close correlation, with a coefficient as high as $r = 0.56$ ($p < 0.001$), was also observed between the serum Alb levels and the total lymphocyte count in patients with esophageal cancer. Since the visceral proteins, minerals, vitamin A, and immunocompetence are all decreased with the progression of the clinical stage in patients with esophageal cancer, sufficient nutritional support is mandatory.

The incidence of anastomotic leakage in this series was 6.0% (22/364), but in esophageal cancer patients, the incidence of anastomotic leakage was surprisingly high (11/50, 22%), and in four patients this resulted in death. Several technical variations, both in surgical procedure and in the perioperative care of the patients with esophageal cancer, have been employed since 1984, such as reconstruction through the posterior mediastinum, selective endobronchial intubation during surgery, strict fluid restriction (40–45 mL/kg/d) until the third postoperative day, and immediate total parenteral and/or enteral nutrition after surgery. For the last 2 years, we have seen no life-threatening major complications such as leaks or respiratory failure, but in seven patients, some minor complications have occurred. These have included chylothorax, myocardial infarction, wound dehiscence, recurrent nerve paralysis, atelectasis, bronchopneumonia, and pleuritis. The incidence of minor complications with esophagectomy was calculated as 27%, and none of these esophagectomized patients died within 1 month of the operation. Furthermore, no postoperative hospital deaths have occurred for the past 2 years.

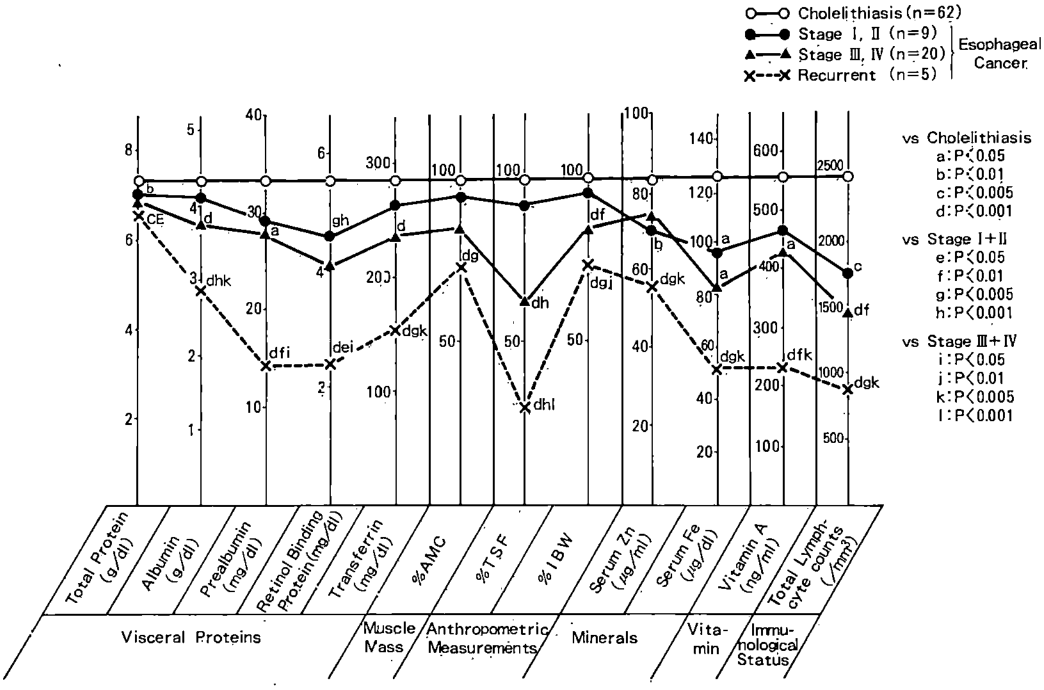

FIG. 9. Nutritional and immunologic parameters in patients with esophageal cancer of different stage. Patients with cholelithiasis were used as a control group. Results are given as the mean values.

Discussion

In surgical patients, a catabolic response occurs as a result of the stress hormones released after surgery in proportion to the magnitude of stress. However, the half-lives of several stress hormones in plasma are so short (minutes) that scrupulous caution is needed in measuring them. For example, the half-life of the plasma catecholamines is extremely short, less than 2 minutes after release into the bloodstream.[11]

It has been previously reported that there is a significant correlation between the plasma concentrations of NE at maximum levels and the magnitude of stress such as the type of operative procedure, blood loss during surgery, and the duration of surgery.[10] We found no correlation among these factors, leading us to presume that there were differences in the times of measurement. The plasma catecholamine levels in surgical patients fluctuate in response to the kind of anesthesia used, the volume of blood lost during surgery, and the posture of the patients during surgery.[12,13] In general, epidural anesthesia may inhibit plasma catecholamine secretion and, therefore, reduce the postoperative catabolic response, whereas the levels of plasma catecholamine are increased by the induction of neuroleptanalgesia.[14] The plasma NE levels during surgery are not an accurate index for the magnitude of the surgical stress. Generally speaking, it is thought that delayed and inadequate responsiveness, prolonged recovery from the catabolic phase, and poor adaptation are the characteristic features of elderly patients with respect to their metabolic response to surgical stress. In the present study, however, we found that although the response pattern to surgical stress in elderly patients is not essentially different from that of patients under 70 years, the peak levels of stress hormones are retarded and diminished in the elderly. Furthermore, it becomes evident that the poor correlation in the aged group between the plasma aldosterone levels and the urinary Na/K ratio may reflect a retarded response to the hormone or a primary loss of function of the target organ.

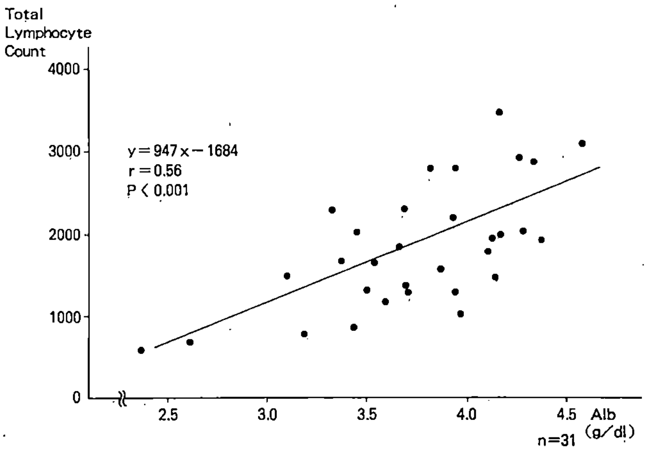

FIG. 10. Correlation between total lymphocyte count in peripheral blood and serum albumin levels in patients undergoing esophagectomy for cancer.

If the excess response of the sympathetic nervous system and adrenal axis to surgical stress could be suppressed, more stable cardiopulmonary function during surgery and a reduction in the excessive and undesirable catabolic reactions after surgery might be achieved. Berk et al.[15] have suggested that the use of β-adrenergic blockers could reduce these catabolic reactions. Further studies on the proper anesthesia and surgery to minimize the stress response are required.

The many risk factors that contribute to postoperative complications following esophagectomy with thoracotomy for cancer have been listed in the literature.[16] Among these factors, chronic bronchitis and preoperative irradiation have been particularly significant risks that increase the chance of the postoperative development of pulmonary complications. The present study discloses that there is a significant correlation between the postoperative development of complications and the preoperative impairment of the respective organs in aged patients. With respect to perioperative replacement therapy, it is clearly necessary to maintain an adequate circulating blood volume and to prevent acute renal insufficiency during and after surgery. Therefore, sufficient infusions should be given to prevent early postoperative hypovolemia, as proposed by Ando et al.[17] However, until the third postoperative day, it is recommended to restrict fluids as evidenced by the present studies on hormonal response.

Since the pulmonary complications following the use of mechanical ventilation postoperatively increase significantly with its duration, one must take this into consideration. Recently, it has been advocated that selective endobronchial intubation was associated with fewer postoperative pulmonary complications than endotracheal intubation. Our results in this series confirmed these reports.

The improvement of the nutritional status of patients with cancer through nutritional support can reduce the operative mortality and morbidity rates. Nutritional assessment is important for this purpose. It is essential in the formulation of nutritional supplements and in judging its effects for rational preoperative and postoperative nutritional support.

In general, the average nutritionally depleted or complicated cancer patients requires between 40 and 50 kcal/kg/d with simultaneous administration of 150 to 200 nonprotein calories/g nitrogen.

If the poor nutritional status of cancer patients on admission can be improved by adequate preoperative nutritional support, the incidence of postoperative complications, including anastomotic leakage, can be considerably reduced.

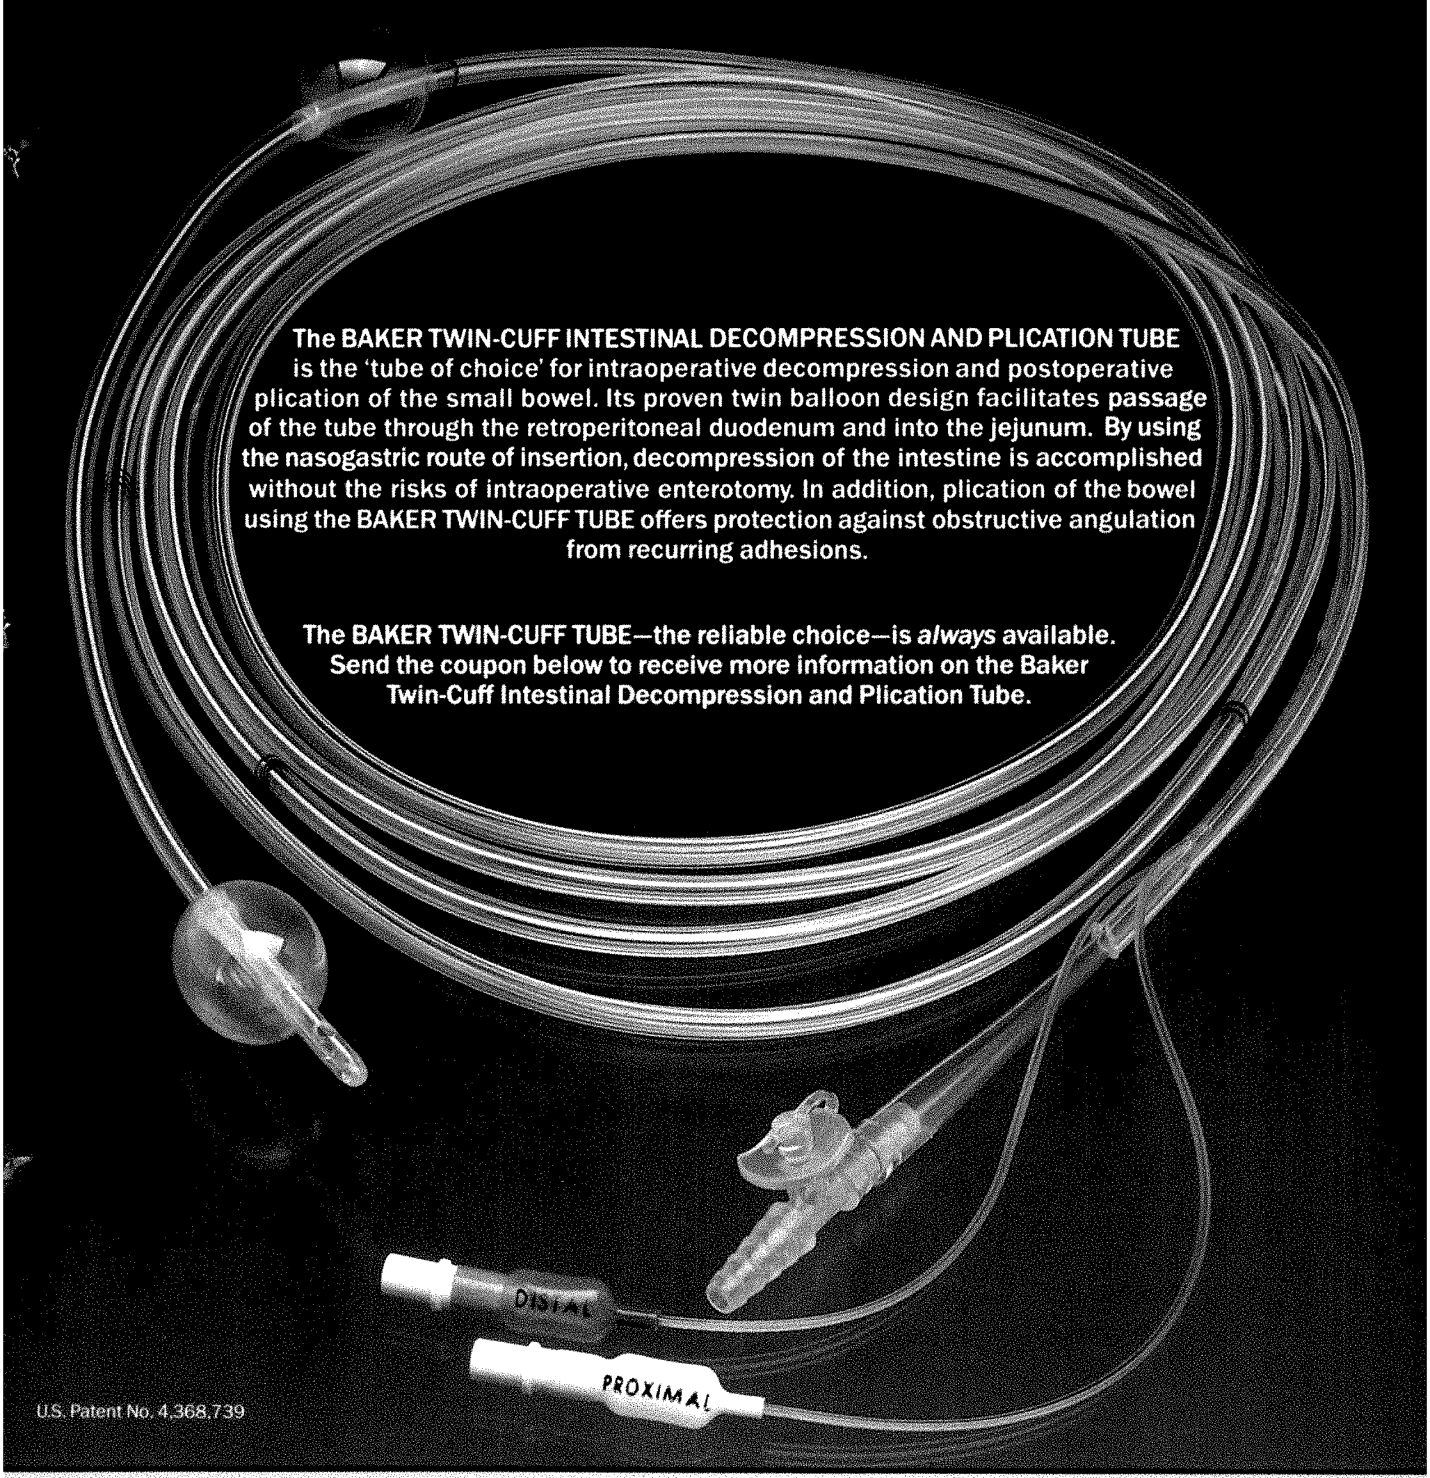
DECOMPRESSION AND PLICATION TUBE



The BAKER TWIN-CUFF INTESTINAL DECOMPRESSION AND PLICATION TUBE is the 'tube of choice' for intraoperative decompression and postoperative plication of the small bowel. Its proven twin balloon design facilitates passage of the tube through the retroperitoneal duodenum and into the jejunum. By using the nasogastric route of insertion, decompression of the intestine is accomplished without the risks of intraoperative enterotomy. In addition, plication of the bowel using the BAKER TWIN-CUFF TUBE offers protection against obstructive angulation from recurring adhesions.

The BAKER TWIN-CUFF TUBE—the reliable choice—is *always* available. Send the coupon below to receive more information on the Baker Twin-Cuff Intestinal Decompression and Plication Tube.

U.S. Patent No. 4,368,739

Once the tip of the tube has been advanced to the second portion of the duodenum, the proximal balloon, which is still in the stomach, can be grasped and pushed through the pylorus. As the proximal balloon approaches the second portion of the duodenum the distal balloon can be grasped at the ligament of Treitz and the tip of the tube advanced into the jejunum.

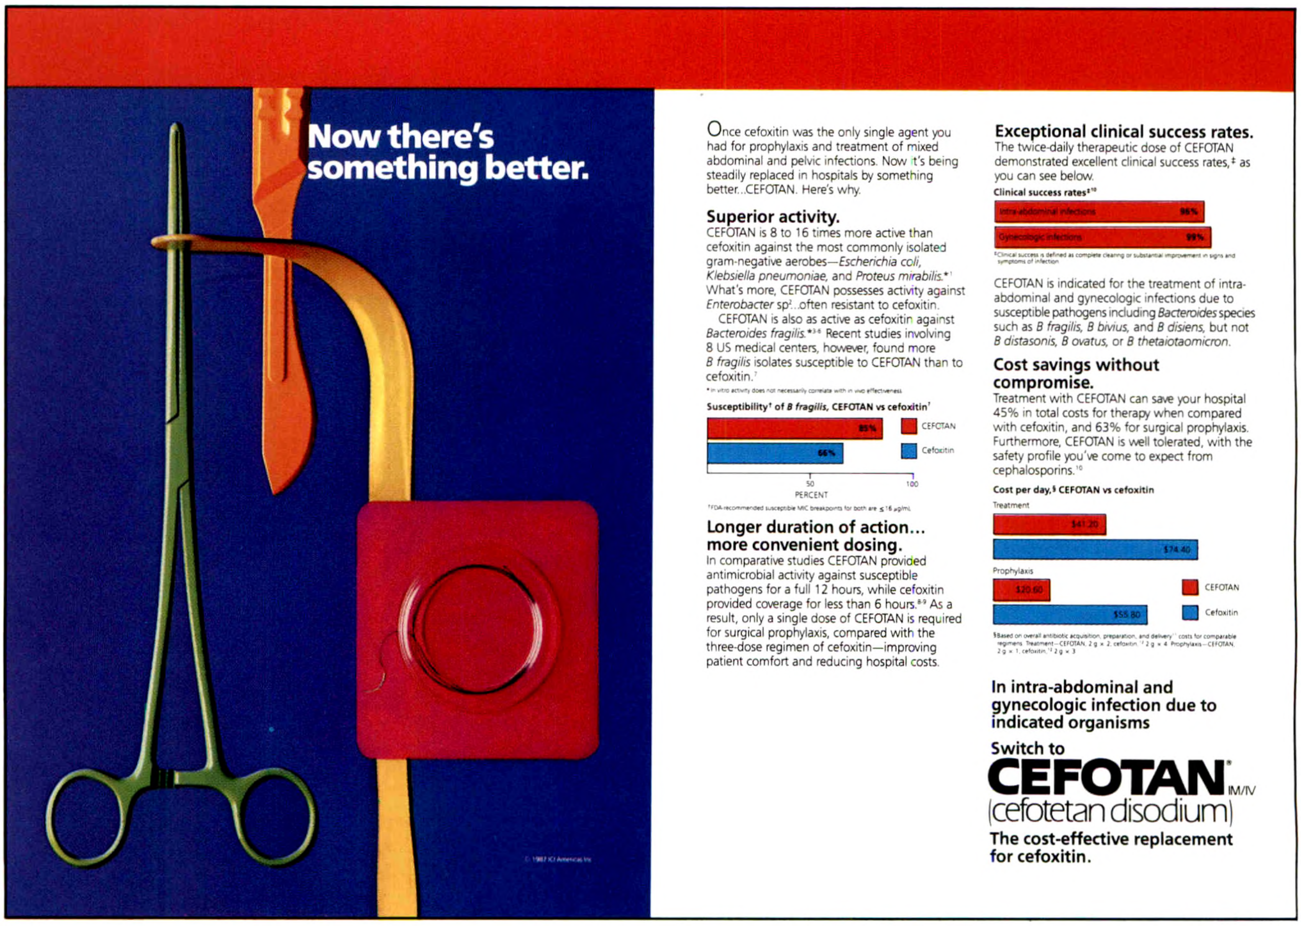
We said.[1]



Now there's something better.

Once cefoxitin was the only single agent you had for prophylaxis and treatment of mixed abdominal and pelvic infections. Now it's being steadily replaced in hospitals by something better...CEFOTAN. Here's why.

Superior activity.

CEFOTAN is 8 to 16 times more active than cefoxitin against the most commonly isolated gram-negative aerobes—*Escherichia coli, Klebsiella pneumoniae*, and *Proteus mirabilis*.*[1] What's more, CEFOTAN possesses activity against *Enterobacter* sp[2]...often resistant to cefoxitin.

CEFOTAN is also as active as cefoxitin against *Bacteroides fragilis*.*[3-6] Recent studies involving 8 US medical centers, however, found more *B fragilis* isolates susceptible to CEFOTAN than to cefoxitin.[7]

*In vitro activity does not necessarily correlate with in vivo effectiveness.

Susceptibility† of *B fragilis*, CEFOTAN vs cefoxitin[7]

†FDA-recommended susceptible MIC breakpoints for both are ≤16 μg/mL

Longer duration of action... more convenient dosing.

In comparative studies CEFOTAN provided antimicrobial activity against susceptible pathogens for a full 12 hours, while cefoxitin provided coverage for less than 6 hours.[8-9] As a result, only a single dose of CEFOTAN is required for surgical prophylaxis, compared with the three-dose regimen of cefoxitin—improving patient comfort and reducing hospital costs.

Exceptional clinical success rates.

The twice-daily therapeutic dose of CEFOTAN demonstrated excellent clinical success rates,‡ as you can see below.

Clinical success rates‡[10]

‡Clinical success is defined as complete clearing or substantial improvement in signs and symptoms of infection

CEFOTAN is indicated for the treatment of intra-abdominal and gynecologic infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis, B bivius*, and *B disiens*, but not *B distasonis, B ovatus*, or *B thetaiotaomicron*.

Cost savings without compromise.

Treatment with CEFOTAN can save your hospital 45% in total costs for therapy when compared with cefoxitin, and 63% for surgical prophylaxis. Furthermore, CEFOTAN is well tolerated, with the safety profile you've come to expect from cephalosporins.[10]

Cost per day,§ CEFOTAN vs cefoxitin

§Based on overall antibiotic acquisition, preparation, and delivery[11] costs for comparable regimens. Treatment—CEFOTAN, 2 g × 2; cefoxitin,[12] 2 g × 4. Prophylaxis—CEFOTAN, 2 g × 1; cefoxitin,[12] 2 g × 3

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV
(cefotetan disodium)

Does so much for so much less than cefoxitin

Please see next page for brief summary of prescribing information.

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV

(cefotetan disodium)

Does so much for so much less than cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,** *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,** *Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.*†
***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.
† Efficacy for this organism in this organ system was studied in fewer than ten infections.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

Treatment of the Dumping Syndrome with the Somatostatin Analogue SMS 201-995

WIM P. M. HOPMAN, M.D., PH.D.,* RUUD G. J. WOLBERINK, M.D.,* CORNELIS B. H. W. LAMERS, M.D., PH.D.,*‡ and JAN H. M. VAN TONGEREN, M.D., PH.D.*

From the Department of Gastroenterology and Hepatology, University Hospital Nijmegen, Nijmegen, The Netherlands, and the Department of Gastroenterology and Hepatology, University Hospital Leiden, Leiden, The Netherlands†*

In six patients suffering from severe early dumping and six patients with late dumping after peptic ulcer surgery, the effect of the somatostatin analogue SMS 201-995 was compared with placebo. In early dumpers subcutaneous administration of 50 µg SMS 201-995 prior to meal ingestion induced a strong improvement of dumping symptoms as reflected by a decrease of the Sigstad dumping score from 12 $\pm$ 2 during placebo to 5 $\pm$ 2 ($p < 0.05$). Furthermore, the postprandial increase of pulse rate was abolished; maximum pulse rate decreased from 85 $\pm$ 7 beats/min to 67 $\pm$ 7 beats/min ($p < 0.05$). SMS 201-995 did not significantly affect postprandial changes in packed cell volume. In late dumpers 50 µg SMS 201-995 reduced peak plasma insulin after oral glucose from 173 $\pm$ 16 mU/L during placebo to 35 $\pm$ 9 mU/L during SMS 201-995 ($p < 0.05$) and increased individual plasma glucose nadirs from 1.9 $\pm$ 0.3 mmol/L to 7.5 $\pm$ 3.3 mmol/L ($p < 0.01$). Both in early and late dumpers SMS 201-995 improved postprandial expiratory breath hydrogen excretion indicating slowing of gastrointestinal hurry. SMS 201-995 is a powerful therapeutic agent for the management of patients suffering from the dumping syndrome after gastric surgery.

THE DUMPING SYNDROME can be a serious and disabling complication after gastric surgery.[1–3] The syndrome is precipitated especially by heavy or carbohydrate-rich meals (1–3). Symptoms of early dumping occur during or immediately after meal ingestion and consist of both gastrointestinal and cardiovascular components including nausea, epigastric distress, meteorismus, borborygmia, palpitation, weakness, exhaustion, dyspnea, dizziness, and syncope.[2] The symptoms of late dumping including a feeling of warmth, sweating, shakiness, dizziness and difficulty in concentration occur 1 to 3 hours later and are attributed to reactive postprandial hypoglycemia.[3] Rapid gastric emptying of hyperosmolar food resulting in a shift of water and elektrolytes to the small intestinal lumen with subsequent hemoconcentration and abnormal gut endocrine responses are generally thought to play a crucial role in the pathogenesis of the syndrome.[1–7] So far, methods of treatment including dietary fibers and α-glucosidase inhibitors have met with only limited success.[8–11] Recently, it has been suggested that somatostatin and possibly its analogues might be of value in the management of circulatory and metabolic disturbances associated with the syndrome.[12] The present study was therefore undertaken to determine the effect of SMS 201-995, a long-acting analogue of somatostatin, on clinical symptoms, pulse rate, packed cell volume, plasma insulin, plasma glucose, and breath hydrogen excretion in patients suffering from postprandial dumping.

Patients and Methods

Six patients (three men, three women; 33–48 years) with early dumping selected on the basis of the clinical diagnostic index divised by Sigstad[13] participated in the study. All patients had undergone a partial gastric resection for peptic ulcer disease at least 1 year before. In addition, six patients (three men, three women; 26–48 years; one highly selective vagotomy, five partial gastrectomy) with late dumping were studied. These patients were selected on the basis of having a history suggestive of postprandial hypoglycemia, a plasma glucose of less than 3.0 mmol/L at least 60 minutes after ingestion of 50 g glucose/m^2 body surface, and hypoglycemic

Submitted for publication: August 13, 1987.

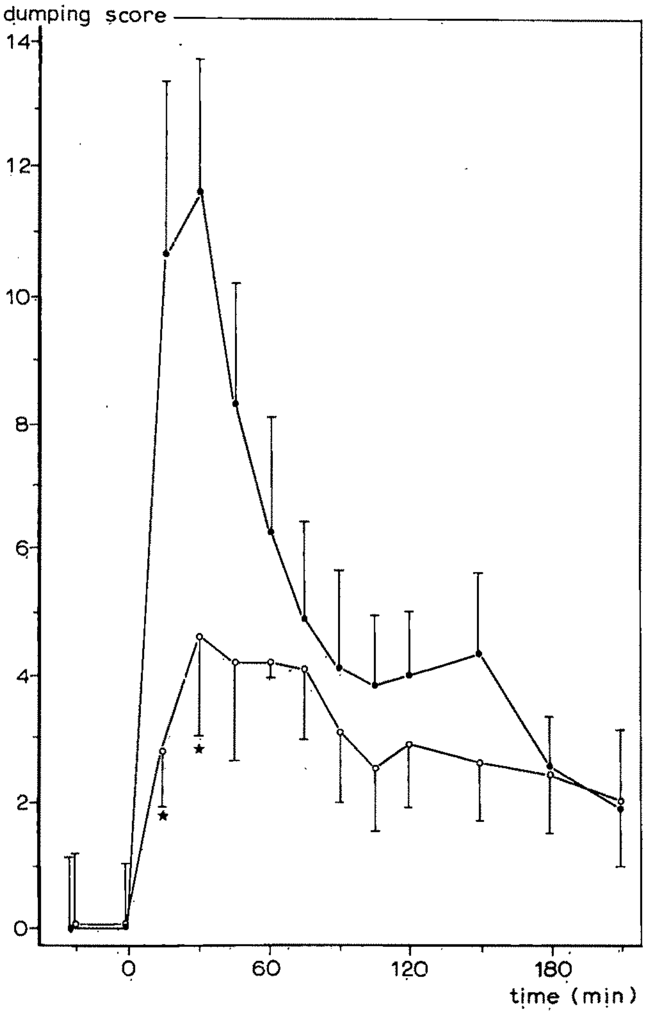

FIG. 1. Numerical dumping score after oral glucose with SMS 201-995 (O) and without SMS 201-995 (●) in six patients with early dumping. *Significant differences from placebo.

symptoms at least 60 minutes after the oral glucose load. Each patient was studied on two occasions after an overnight fast. In random order and in a double-blind fashion either 50 μg SMS 201-995 or placebo was administered subcutaneously 15 minutes before ingestion of 50 g glucose/m^2 body surface. Before ingestion of the 50% glucose solution in water and at regular intervals thereafter, patients were questioned about their symptoms and allocated a dumping score according to Sigstad.[13] Pulse rate was counted and blood samples were drawn at −25, −20, −15, 0, 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, 180, 195, and 210 minutes. Before ingestion of the meal and at 30-minute intervals during the study, end-expiratory gas samples were obtained for measurement of breath hydrogen.[14] In the patients with early dumping the blood samples were used to measure packed cell volume. In patients with late dumping, these samples served to measure plasma glucose and plasma insulin levels.[15] Packed cell volume and plasma glucose were measured by standard techniques.

Results were expressed as the mean ± 1 SEM. Statistical analysis was performed by Student's t-test for paired results. Wilcoxon's test for paired data was used to analyse dumping score. All patients gave informed consent before entering the study. The study was approved by the local ethical committee.

Results

Early Dumpers

During placebo injection dumping score increased to a peak value of 11.7 ± 2.1 at 30 minutes after meal ingestion indicating severe dumping (Fig. 1). During SMS 201-995 all patients experienced a dramatic improvement of postprandial symptoms. At 15 and at 30 minutes, dumping score during SMS 201-995 was sig-

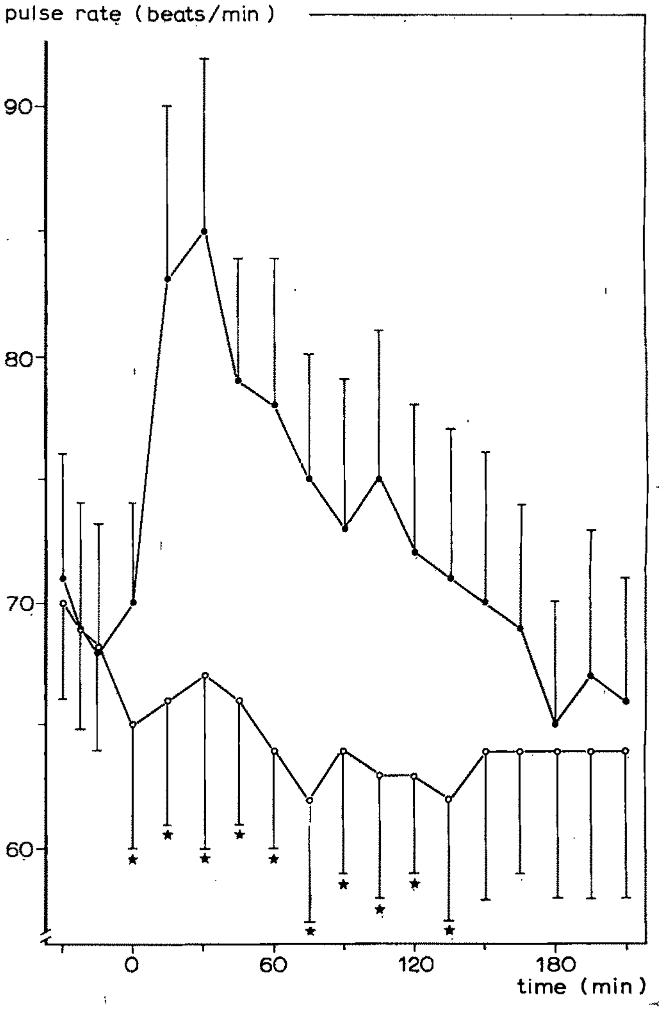

FIG. 2. Pulse rate after oral glucose with SMS 201-995 (O) and without SMS 201-995 (●) in six patients with early dumping. *Significant differences from placebo.

nificantly lower than that during placebo ($p < 0.05$, Fig. 1). Maximum dumping score during SMS 201-995 was 4.6 ± 1.6 at 30 minutes ($p < 0.05$ *vs.* placebo). Pulse rate increased from a basal value of 70 ± 4 beats/min to a maximum value of 85 ± 7 beats/min at 30 minutes after meal ingestion during placebo ($p < 0.05$, Fig. 2). On the other hand, SMS 201-995 abolished this postprandial rise in pulse rate (Fig. 2). Pulse rate during SMS 201-995 was significantly lower than that during placebo from 0 to 135 minutes ($p < 0.05$ to $p < 0.005$, Fig. 2).

Packed cell volume rose from 0.38 ± 0.02 L/L to 0.41 ± 0.02 L/L at 30 minutes during placebo ($p = 0.0005$, Fig. 3), and from 0.39 ± 0.02 L/L to 0.41 ± 0.02 L/L during SMS 201-995 ($p < 0.05$, Fig. 3). No significant differences were observed between packed cell volume during placebo and packed cell volume during SMS 201-995.

Four patients had a breath hydrogen excretion of more than 15 ppm during placebo at 30–60 minutes indicating spillover of glucose to the colon, but only one patient during SMS 201-995 at 150 minutes.

Late Dumpers

In patients suffering from reactive hypoglycemia, the initial rapid rise in plasma glucose was followed by a sharp decline to levels below 3.0 mmol/L from 105 to 135 minutes after the oral glucose load (Fig. 4). The reactive hypoglycemia observed during the placebo study was completely abolished by subcutaneous administration of SMS 201-995. From 60 to 210 minutes plasma glucose during SMS 201-995 was significantly higher than that during placebo ($p < 0.05$ to $p < 0.0005$, Fig. 4). Individual plasma glucose nadirs during placebo were 1.9 ± 0.3 mmol/L. During SMS 201-995 lowest individual plasma glucose levels were 7.5 ± 3.3 mmol/L ($p < 0.001$). SMS 201-995 attenuated plasma insulin response to glucose ingestion. Plasma insulin during SMS 201-995 was significantly lower than that during placebo at 30 and at 60 minutes ($p < 0.05$ to $p < 0.01$, Fig. 5). Peak plasma insulin level decreased from 173 ± 16 mU/L during placebo to 35 ± 9 mU/L during SMS 201-995 ($p < 0.05$). No patient experienced hypoglycemic symptoms during SMS 201-995. Three patients had a breath hydrogen excretion of more than 15 ppm during placebo at 15–60 minutes. On the other hand, during SMS 201-995 no patient presented with abnormal breath hydrogen excretion.

Discussion

SMS 201-995 is a recently developed, long-acting analogue of somatostatin.[16] The circulating half-life of SMS 201-995 of about 100 minutes after subcutaneous injection is substantially longer than that of native somato-

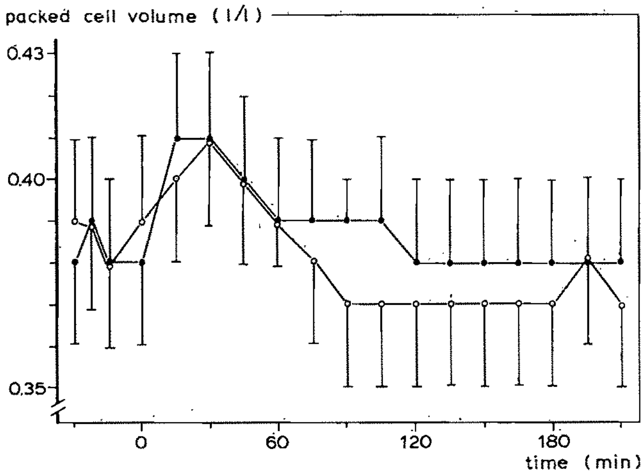

FIG. 3. Packed cell volume after oral glucose with SMS 201-995 (O) and without SMS 201-995 (●) in six patients with early dumping.

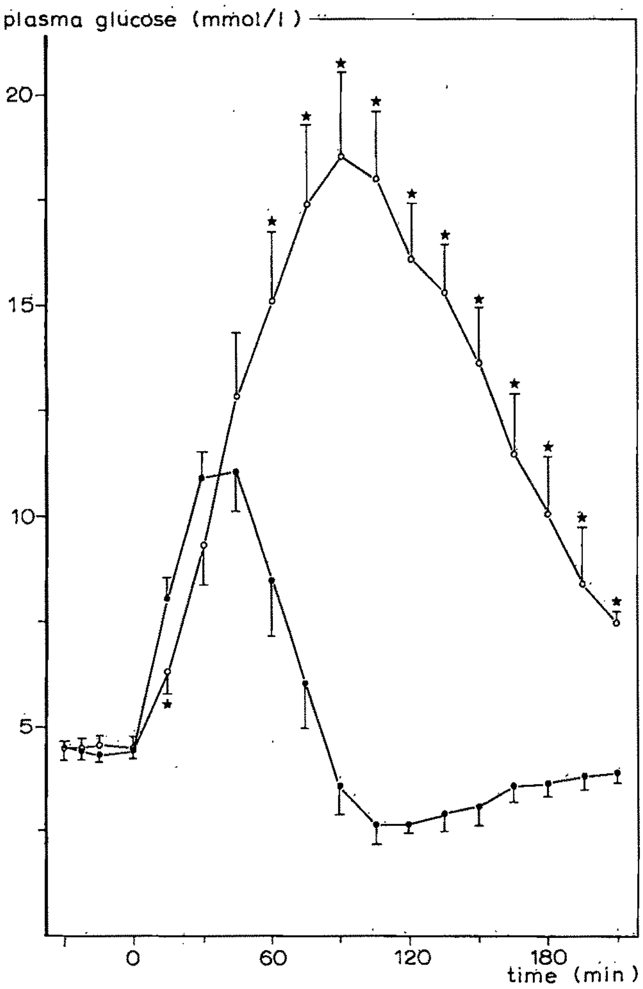

FIG. 4. Plasma glucose after oral glucose with SMS 201-995 (O) and without SMS 201-995 (●) in six patients with late dumping. *Significant differences from placebo.

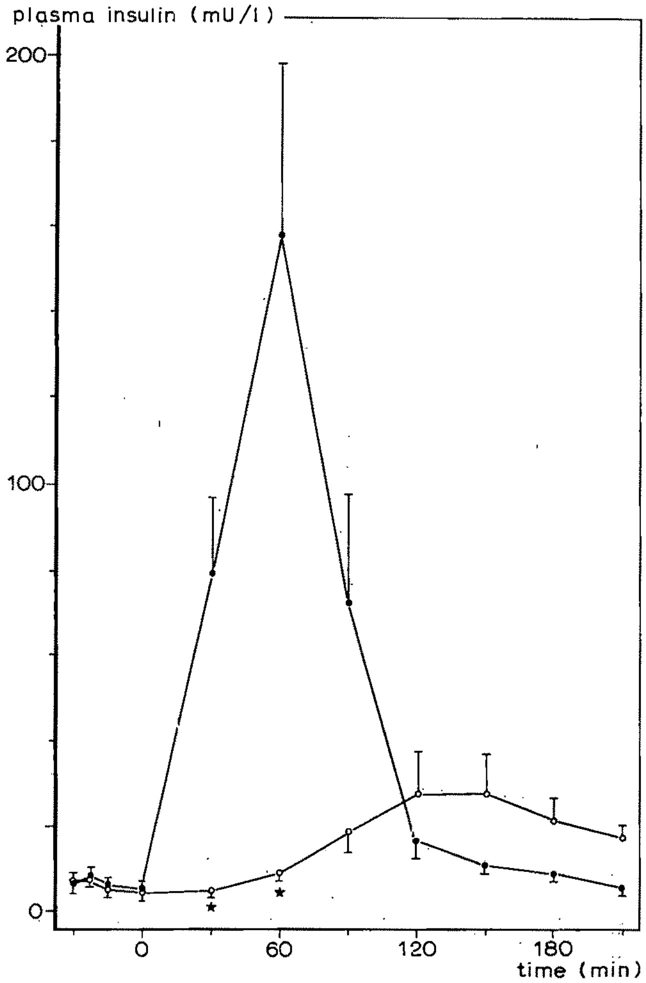

FIG. 5. Plasma insulin after oral glucose with SMS 201-995 (O) and without SMS 201-995 (●) in six patients with late dumping. *Significant differences from placebo.

statin, which is only 2 to 3 minutes.[16] SMS 201-995 inhibits release of growth hormone, and it has been used successfully in the treatment of patients with acromegaly.[17] Similar to native somatostatin, SMS 201-995 inhibits release of several gastrointestinal peptides including insulin, glucagon, gastrin, gastric inhibitory polypeptide, pancreatic polypeptide, vasoactive intestinal polypeptide, and neurotensin.[18] SMS 201-995 was found to have a beneficial effect in the management of patients with insulinoma, glucagonoma, VIPoma, and carcinoid syndrome.[19,20]

The present study shows a dramatic improvement of postprandial dumping symptoms after subcutaneous injection of SMS 201-995 prior to meal ingestion in patients with previous gastric surgery. All patients with early dumping participating in the study suffered from severe postprandial complaints that had resisted other therapeutic efforts including addition of pectin or acarbose, an α-glucosidase inhibitor, to the meal. In these patients dumping score decreased from 12 to 5. McLoughlin et al.[9] treated patients with less severe dumping symptoms with acarbose. In these patients an improvement of the dumping score from only 6 to 4 was reported. Furthermore, during SMS 201-995, postprandial rise of pulse rate, a symptom associated with the dumping syndrome, was completely abolished. This action agrees with that of native somatostatin in dumping patients.[12]

The mechanism by which SMS 201-995 exerts its beneficial effect on postprandial dumping is not known. Somatostatin slows gastrointestinal transit.[21] Since rapid gastric emptying of food is generally considered to be of major importance in precipitating the dumping syndrome, the effect of SMS 201-995 might be mediated by slowing of gastrointestinal transit. Indeed, it was shown in the present study that abnormal breath hydrogen excretion indicating spillover of glucose to the colon, resulting from the rapid transit, became normal in three out of four patients with early dumping. An increase in postprandial splanchnic blood flow, together with a paradoxical increase of subcutaneous blood flow (plus a decrease in circulatory blood volume) has been suggested to be involved in the development of cardiovascular symptoms.[1,2,6] Because postprandial increase of packed cell volume was not significantly affected by SMS 201-995, it is unlikely that SMS 201-995 exerted its beneficial effect by preventing plasma volume depletion. On the other hand, the beneficial effect of SMS 201-995 on circulatory disturbances might be related to a direct pressor effect on splanchnic hemodynamics. Indeed, it was recently reported that SMS 201-995 inhibited splanchnic blood flow similar to native somatostatin.[22,23] Furthermore, a pressor effect of SMS 201-995 was demonstrated in patients suffering from postprandial hypotension.[24] Another possibility is that SMS 201-995 similar to native somatostatin inhibited excessive release of vasoactive substances from the gut that have been incrementated in the pathogenesis of circulatory disturbances.[1,2,4,5,7,12] It is interesting to note that SMS 201-995 also improved circulatory symptoms in patients with the carcinoid syndrome.[20]

In patients suffering from late dumping, SMS 201-995 was highly effective for the prevention of reactive hypoglycemia. Even after administration of a powerful challenge of carbohydrate metabolism by a concentrated glucose meal, during SMS 201-995 the lowest plasma glucose level was well above hypoglycemic values. No complaints of hypoglycemia were reported during SMS 201-995. The beneficial effect of SMS 201-995 is probably related to inhibition of excessive insulin release in the early postprandial phase as demonstrated in the present study. Furthermore, inhibition of intestinal hurry as reflected by breath hydrogen excretion allowing glucose to be present in the small intestine for absorption in the late postprandial phase, probably contributes to the beneficial effect of SMS 201-995. α-Glucosidase inhibitors have been recommended in patients suffering from postprandial reactive hypoglycemia.[9–11] However, these substances induced serious side effects due to malabsorption of carbohydrates.[10,11] In contrast, SMS 201-995 subsided malabsorption of carbohydrates in all patients with late dumping.

Long-term studies have demonstrated good tolerance of SMS 201-995 in the treatment of patients with acromegaly, carcinoid syndrome, and other endocrine tumors of the gut.[17,19,20,24,25] In these patients no serious side effects were reported. Similarly, in the present study SMS 201-995 was well tolerated by all patients without any side effects.

We conclude that SMS 201-995 is highly effective for the prevention of symptoms and signs related to the dumping syndrome. It reduces tachycardia and peak plasma insulin level, and it prevents reactive hypoglycemia with spillover of glucose to the colon. Since SMS 201-995 is well tolerated, it holds promise as a powerful therapeutic agent in patients with disabling postprandial dumping after previous gastric surgery.

Acknowledgments

Intraoperative Ultrasonographic Localization of Islet Cell Tumors

A Prospective Comparison to Palpation

JEFFREY A. NORTON, M.D.,* DOUGLAS T. CROMACK, M.D.,* THOMAS H. SHAWKER, M.D.,† JOHN L. DOPPMAN, M.D.,† RICHARD COMI, M.D.,‡ PHILLIP GORDEN, M.D.,‡ PAUL N. MATON, M.D.,§ JERRY D. GARDNER, M.D.,§ and ROBERT T. JENSEN, M.D.§

The purpose of the present study was to evaluate prospectively the value of intraoperative ultrasound scanning (IOUS) in localizing islet cell tumors by comparing results of IOUS to those of palpation during 44 consecutive laparotomies for gastrinoma (36) or insulinoma (8). All patients had preoperative radiographic imaging studies and selective venous sampling for hormones, which guided the subsequent laparotomy. Any suspicious finding by palpation and/or IOUS was resected. Pathologic evidence of islet cell neoplasm served as the reference standard. Five patients were excluded from analysis because neither palpation nor IOUS had suspicious findings and no islet cell tumor was found. Seven pancreatic insulinomas were found in seven patients. IOUS was as sensitive as palpation at localizing insulinomas. Twenty-three pancreatic gastrinomas were found in 19 patients. IOUS was equal to palpation in the ability to localize gastrinomas. Gastrinomas that were successfully imaged by IOUS were significantly larger than gastrinomas that were not imaged. Twelve extrapancreatic gastrinomas were found in nine patients, and palpation was more sensitive than IOUS at localizing these small duodenal wall tumors. Five patients (11%) had their surgical management changed by IOUS. Two patients had pancreatic tumors (one gastrinoma and insulinoma) enucleated that would not have been found without IOUS, and three patients had resections of pathologically proven malignant islet cell tumors based on sonographic findings. All five patients were *cured* with short follow-up. The present results demonstrate that palpation and IOUS are complementary because IOUS can image tumors that are not palpable and IOUS can provide additional information concerning malignant potential not detected by palpation.

TUMOR LOCALIZATION is a major problem associated with endocrine tumors. Small islet cell tumors produce hormones that lead to early diagnosis and potential surgical intervention. Despite careful search at laparotomy, insulinomas and gastrinomas are occult and elusive. Blind subtotal pancreatectomy with the increased morbidity and mortality rate is necessary when an insulinoma cannot be found.[1] Gastrinomas are more elusive than insulinomas and have been localized in only 60–73% of laparotomies for Zollinger-Ellison syndrome (ZES).[2-4] Preoperative localization procedures, including selective arteriography,[5] CT scanning with contrast,[6] and transhepatic portal venous sampling for hormones,[7] have not solved the problem of islet cell tumor localization.

In 1982 the use of high-resolution B-mode IOUS scanning to image an insulinoma[8] and a gastrinoma[9] was first reported. In 1985 operative sonography successfully localized a small insulinoma, which had not been palpable in the pancreatic head.[10] We have had a large experience with insulinoma[11] and gastrinoma.[12] To evaluate the potential usefulness of IOUS to find small, surgically curable insulinomas and gastrinomas, we instituted a prospective comparison of IOUS to palpation in 1983. We have briefly described the first 10 gastrinoma patients.[13] We now analyze our results in 44 consecutive patients: 36 patients with gastrinoma and 8 patients with insulinoma.

Methods

In October 1983, a prospective study of the ability of IOUS to localize islet cell neoplasms in patients with either insulinoma or gastrinoma was instituted. All patients were treated at the National Institutes of Health using approved protocols.

Submitted for publication: August 14, 1987.

The diagnosis of insulinoma was established by an inappropriate elevation of serum insulin level and hypoglycemia following a fast.[11] The diagnosis of ZES was established using the following criteria: (1) elevated fasting serum gastrin concentration (> 100 pg/mL); (2) basal acid output greater than 15 mEq/h (no previous gastric surgery); and (3) abnormal provocative secretin or calcium test defined as an increase in serum gastrin concentration of greater than 200 pg/mL following the I.V. administration of 2 U/kg of GIH secretin or greater than 395 pg/mL after calcium (5 mg/kg/h × 3 hours).[4]

All patients had preoperative localization studies, namely, ultrasound, computed tomography, selective ateriography, and percutaneous transhepatic portal venous sampling (PVS).[4–8] A hormone (either gastrin or insulin) gradient of 50% (selective portal venous hormone concentration/simultaneous peripheral venous concentration) was considered to be regionally localizing to the head, body, or tail of the pancreas.[7] As outlined previously,[4] all patients with metastatic tumor to the liver or with multiple endocrine neoplasia type I without positive results from imaging studies were excluded from this study. Final surgical pathology served as the reference standard for all intraoperative localization maneuvers.

All operations were performed as previously described.[4] The liver, pelvis, small intestine, pancreas, stomach, duodenum, mesenteric, and retroperitoneal regions were carefully explored. The pancreas was examined visually and by palpation. The pancreatic head was inspected after an extended Kocher maneuver. The pancreatic body and tail were inspected by opening the lesser sac along the avascular plane of the transverse colon. The inferior border of the pancreas was dissected free, so the body and tail could be palpated between two fingers. The entire duodenum was carefully palpated. The same extensive search was made regardless of the preoperative localization information or the operative findings. Knowledge of the preoperative imaging and localization studies did guide the exploration in that a general exploration was performed on all patients, but specific areas were focused based on preoperative imaging. Any suspicious finding by palpation was noted, and subsequently following ultrasound was excised or resected for pathologic analysis.

FIG. 1. Flow diagram describing the number of patients in the study divided into tumor types, suspicious operative findings, and the numbers of tumors proven pathologically in different patients. †Five patients were excluded from analysis because no tumors were found and no suspicious operative findings were identified by palpation or IOUS. *Two patients had gastrinomas found both within and outside of the pancreas.

After full operative exposure and completion of manual palpation, realtime IOUS was performed using a Diasonics ultrasound scanner (model DRF 1; Diasonics Inc., Milipitas, CA) and a 10 MHz mechanical-sectoring transducer. Realtime studies were recorded on videotape. The transducer was inserted into a long, sterile, plastic sleeve containing methylcellulose gel at the distal tip. The abdominal cavity was filled with warm saline to provide additional acoustic coupling. The pancreas was scanned by passing the probe from the pancreatic head across the body to the tail, visualizing the pancreas in the longitudinal (sagittal) scanning plane. Several parallel passes were necessary for complete examination of the pancreas. Next, the pancreatic head, uncinate process, and duodenum were manually manipulated for optimal exposure and ultrasound visualization. All suspicious findings from palpation were carefully delineated by IOUS examination. The IOUS study was considered positive for islet cell tumor if a sonolucent mass lesion could be detected in both transverse and longitudinal imaging planes. After completion of the IOUS examination, the pancreas and peripancreatic tissues were again carefully palpated. Duodenal nodules were better exposed by opening the duodenal wall. Any suspicious pancreatic, stomach, duodenal, bowel, peripancreatic nodule, or lymph node, whether detected by palpation or intraoperative ultrasound, was biopsied. In the bowel or stomach wall, a suspected tumor was excised with a full thickness rim of normal tissue around the tumor. In the pancreatic head or adjacent lymph node areas, suspected tumors were enucleated. In the pancreatic body and tail, a pancreatic resection or enucleation was performed dependent on the size and appearance of the tumor. Lesions thought to be malignant were resected by subtotal or distal pancreatectomy and splenectomy.

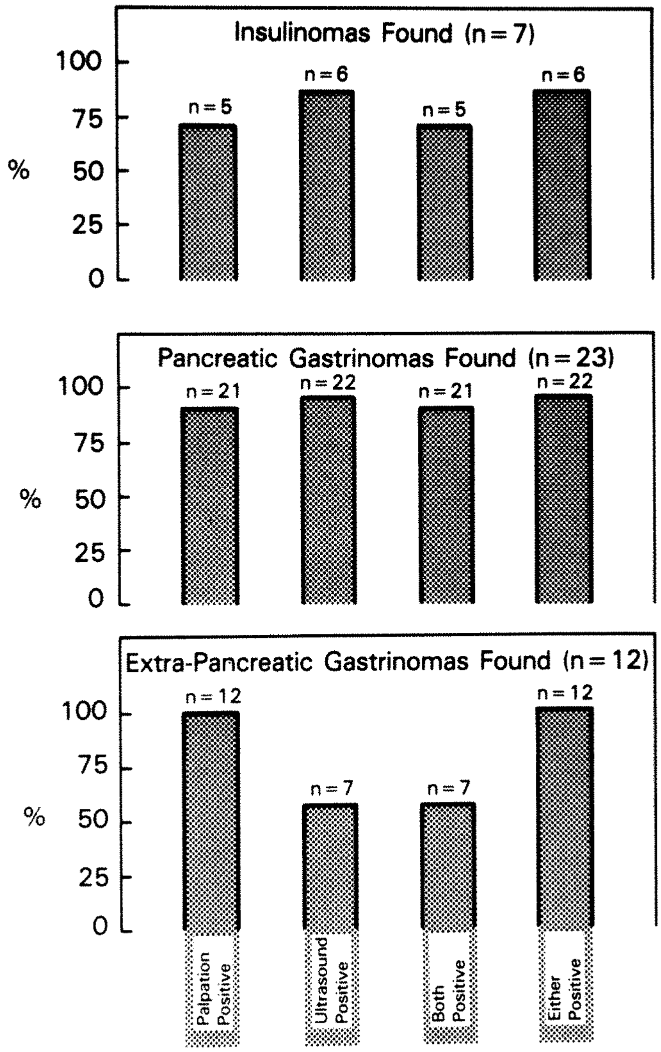

FIG. 2. Percentages for true-positives of operative localization methods including palpation alone, ultrasound alone, both combined and either positive in finding pancreatic insulinomas, pancreatic gastrinomas, and extrapancreatic gastrinomas. Statistically, both operative methods are comparable in finding pancreatic insulinomas and gastrinomas. Palpation is significantly better at localizing extrapancreatic gastrinomas than ultrasound ($p < 0.01$).

Results of intraoperative localization procedures (palpation and ultrasound) were compared to the final surgical, pathologic, and diagnostic proof of islet cell tumor. A decision analysis was performed on the results of intraoperative localization procedures using a method described by Weinstein and Fineberg.[14] After the pathologic results of the operation were known, manual palpation, or IOUS, were rated as true-positive, true-negative, false-positive, or false-negative. A true-positive result was defined as one in which an islet cell tumor was found in the exact location suggested by the intraoperative procedure. A true-negative result was one in which one localization maneuver suggested that no tumor was present in a given location, while the other localization maneuver suggested that tumor was present and no tumor was identified on biopsy. False-positive results were defined as erroneous tumor locations indicated by intraoperative maneuvers. False-negative results were defined as failure to image or palpate a tumor that was subsequently found. Sensitivity of the two methods was calculated by dividing true-positive results by the sum of true-positive and false-positive results. Sensitivity percentages were compared statistically by the Fischer's exact test. Size of tumors detected and not detected by IOUS were compared by unpaired t-test.

Results

Forty-four patients entered this study. Thirty-six patients had the diagnosis of ZES and eight patients had the diagnosis of insulinoma. All patients underwent exploratory laparotomy for tumor resection. Five patients (one insulinoma, four ZES) were excluded from this analysis because intraoperative localization procedures produced no suspicious findings and islet cell tumors were not found (Fig. 1). Suspicious lesions were identified by palpation and/or operative ultrasound in 39 patients (32 ZES, seven insulinoma) who formed the basis of the present analysis. Seven insulinomas (proven pathologically) were detected in the seven patients with a clinical diagnosis of insulinoma, and all tumors were within the pancreas. Six patients with ZES who had suspicious lesions by operative ultrasound and/or palpation had no gastrinomas proven pathologically. In 26 patients with ZES, 35 gastrinomas were proven pathologically. In 19 patients with ZES, 23 gastrinomas were found within the pancreas and in 9 patients, 12 gastrinomas were extrapancreatic. Two patients with ZES had gastrinomas both within and outside of the pancreas (Fig. 1).

TABLE 1. *Palpation* versus *IOUS in Localizing Insulinomas and Gastrinomas*

	Insulinoma (7)		Gastrinoma (35)	
	Palpation	IOUS	Palpation	IOUS
True-positive	5	6	33	29
True-negative	0	1	5	3
False-positive	1	0	9	11
False-negative	2	1	2	6
Sensitivity* (%)	71	86	94	83

Values in parentheses are the total no. of tumors proven pathologically.

* Sensitivity of palpation *vs.* IOUS at localizing gastrinomas or insulinomas is not significantly different.

Palpation Versus *IOUS to Localize Islet Cell Tumors*

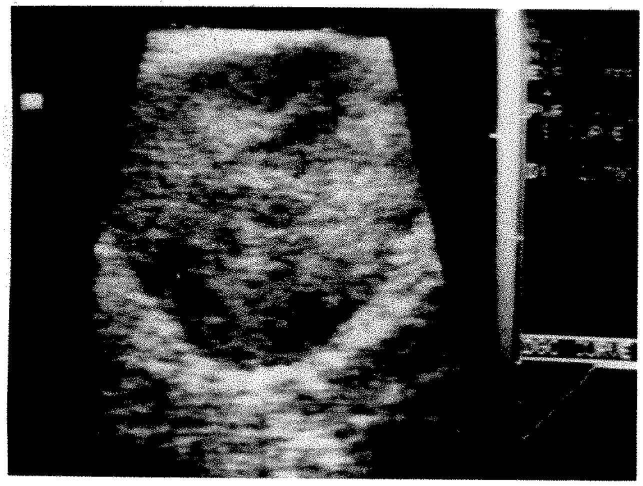
IOUS correctly identified six of seven insulinomas, while palpation only identified five (Fig. 2, Table 1). One insulinoma was not detected by palpation or IOUS and was found following a blind distal pancreatectomy in a patient with a selective insulin gradient in the distal pancreas detected by PVS. The IOUS appearance of most islet cell tumors typically demonstrated a sonolucent mass lesion with discrete echogenic borders (Fig. 3) as described previously.[8-10] Palpation correctly identified 33 of 35 gastrinomas while IOUS only identified 29 (Table 1, Fig. 2). Both methods were equal (sensitivity) in their ability to localize insulinomas and gastrinomas (Table 1). Each method individually was similar to either method alone or both methods together in ability to detect insulinomas or pancreatic gastrinomas (Table 2, Fig. 2). Extrapancreatic gastrinomas were identified better by palpation (12 of 12, sensitivity = 100%) than IOUS (7 of 12, sensitivity = 58%) ($p < 0.01$) (Fig. 2, Table 2).

TABLE 2. *Palpation* versus *IOUS in Localizing Pancreatic and Extrapancreatic Gastrinomas*

	Pancreatic Gastrinoma (23)		Extrapancreatic Gastrinoma (12)	
	Palpation	IOUS	Palpation	IOUS
True-positive	21	22	12	7
True-negative	5	1	0	2
False-positive	4	8	5	3
False-negative	2	1	0	5
Sensitivity (%)	91	95	100	58*

Values in parentheses are the total no. of tumors proven pathologically.

* Palpation is more sensitive than IOUS at localizing extrapancreatic gastrinomas ($p < 0.01$), but the two methods are equal at localizing pancreatic gastrinomas.



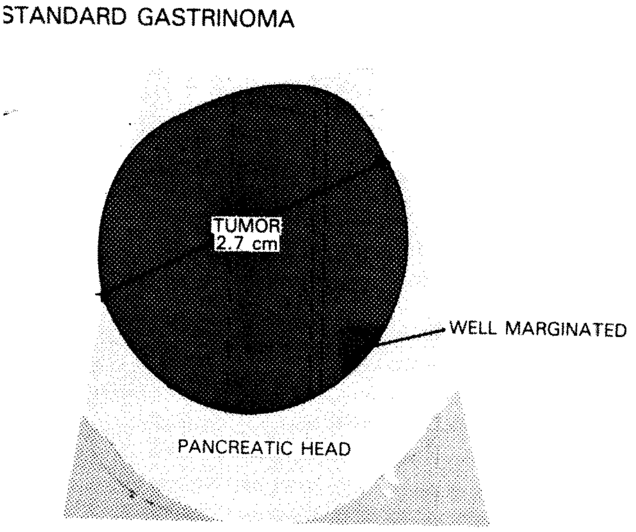


FIG. 3. Operative sonographic appearance of a typical islet cell tumor. The tumor is sonolucent compared to the surrounding pancreas, which is more echogenic. The margin of the tumor and the pancreas is discrete with an echogenic rim around the entire tumor. This appearance is consistent with a benign islet cell neoplasm.

When one combines the pancreatic gastrinomas and insulinomas, 30 islet cell tumors were found within the pancreas. Palpation had 26 true positive findings and IOUS had 28 (Table 3). Sensitivity for palpation (87%) was again similar to sensitivity for IOUS (93%).

False-positive and False-negative Results

False-positive and false-negative localization occurred with both palpation and IOUS for both insulinomas and gastrinomas (Table 1). Whereas the overall rate of either false-positive or false-negative results for palpation and IOUS was not significantly different (Table 3) ($p > 0.1$), analysis of the false-positive cases (Table 4) or false-negative cases (Table 5) demonstrates a number of important features. The duodenum is a common location for gastrinoma, but it was also a common location for ectopic pancreas (three cases) (Table 4), which was identified as a positive tumor in each case by palpation and in one case by IOUS. A 0.5–1.0 cm mass in the pancreatic head area was identified as a gastrinoma in four cases by IOUS and confirmed in one case by palpation, but was found to be a normal intrapancreatic lymph node in the four patients (Table 4). Normal pancreas, scar tissue from previous ulcer disease, and dilated pancreatic ducts were also sources of false-positives (Table 4).

An analysis of the false-negative responses demonstrates that both the size and location of the gastrinoma were important variables (Table 5). The size of the gastrinomas missed by IOUS was significantly smaller than

TABLE 3. *Palpation* versus *IOUS in to Localizing Intrapancreatic Islet Cell Tumors*

	Intrapancreatic Islet Cell Tumors (gastrinomas and insulinomas) (30)	
	Palpation	IOUS
True-positive	26	28
True-negative	5	2
False-positive	5	8
False-negative	4	2
Sensitivity (%)	87	93*

Value in parentheses is the total no. of tumors proven pathologically.

* There is no significant difference between IOUS and palpation.

the size of the gastrinomas correctly identified (0.4 ± 0.05 *vs.* 1.9 ± 0.4 cm, $p < 0.05$, Table 5). Location was important because extrapancreatic gastrinomas were more frequently missed by IOUS than pancreatic gastrinomas (Table 5). Specifically, 1 of 23 pancreatic gastrinomas and 5 of 12 extrapancreatic gastrinomas were missed by IOUS ($p < 0.01$, Table 5). Of the five extrapancreatic gastrinomas missed by IOUS, all five were in the duodenum (Table 5).

Surgical Impact of IOUS

IOUS affected the intraoperative decision process or the ability to find an islet cell tumor in 5 of 44 patients (11%). In three patients (two ZES, one insulinoma), IOUS correctly suggested a malignant gastrinoma that was not obvious by palpation (patients 1, 2, and 5, Table 6). In these patients IOUS demonstrated indistinct margins of the tumor with extension into adjacent pancreas (Fig. 4) and obliteration of the pancreatic duct (Fig. 5). Pancreatic resections were performed based on IOUS findings (Table 6). In two other patients (patients 3 and 4, Table 6) (one with gastrinoma and one with insulinoma), tumors would not have been identified without IOUS. One patient with occult insulinoma in the pancreatic head, which was identified only by IOUS, had been described in detail previously.[10] The other patient with ZES was similar. Portal venous sampling for gastrin suggested that a gastrinoma was located in the pancreatic head region. Careful operative palpation revealed no tumor and a Whipple pancreaticoduodenectomy was not believed to be a reasonable surgical option. Operative ultrasonography revealed a 1-cm sonolucent mass in the posterior head of the pancreas near the common bile duct. The gastrinoma was enucleated with intraoperative ultrasound guidance, and a pancreatic resection was not done. Follow-up of all five patients indicates that each has no evidence of recurrent islet cell tumor.

Discussion

Although IOUS is a recent addition to surgical practice, it is clear that islet cell tumors of the pancreas can be detected intraoperatively by realtime B-mode ultrasonography.[15] The sonographic appearance of islet cell tumors at operation is identical to that described for these tumors detected by ultrasound preoperatively (Fig. 3).[16] The difference in echogenicity between the tumor (typically low echo amplitude) and the pancreas (high echo amplitude) accounts for the visibility of the tumor.[10] Preliminary reports suggest that IOUS has great potential in localizing small islet cell neoplasms[8-10]; yet IOUS is expensive (the equipment in the

TABLE 4. *False-positive Results for Gastrinoma Patients with Palpation and/or IOUS*

Palpation (N = 10)	IOUS (N = 11)	Pathology
2-cm pancreatic tail nodule	2-cm sonolucent lesion	Normal pancreas (no tumor)

present study costs $80,000), requires expertise, and adds time to the operation. Until the present study, no prospective evaluation of IOUS compared to traditional operative techniques such as palpation had been done. The present study demonstrates no overall difference between palpation and ultrasound in the ability to intraoperatively localize pancreatic islet cell tumors; however, it demonstrates that in 11% of patients IOUS provides information not provided by palpation that affects surgical management. For localizing extrapancreatic islet cell tumors, palpation is significantly better than IOUS.

The observed equality between palpation and IOUS in the ability to find pancreatic islet cell tumors was unexpected in light of a number of preliminary reports[8–10,15,17] that IOUS might frequently localize islet

TABLE 6. *IOUS Affected Surgical Decision-making or Ability to Find Islet Cell Tumor*

Patient (N = 5) (11%)	Diagnosis	Impression Postpalpation	IOUS Finding	Surgical Procedure	Pathologic Analysis	Follow-up
1	ZES	Well-defined 2-cm tumor pancreatic tail	2-cm tumor with indistinct margins and extension outside pancreatic tail	Distal pancreatectomy splenectomy	Malignant gastrinoma with vascular invasion and extension outside pancreas into fat	Cured at 6 months
2	ZES	Well-defined 2-cm tumor midpancreatic body	Same 2-cm tumor with invasion into pancreas and extension outside pancreas	Subtotal pancreatectomy splenectomy	Malignant gastrinoma with extension into peripancreatic fat and vascular invasion	Cured at 6 months
3	ZES	No tumor palpable	1-cm well-demarcated tumor in posterior pancreatic head near common duct	Enucleation	1-cm gastrinoma from pancreatic head	Cured at 6 months
4	Insulinoma	No tumor palpable	7-mm well-demarcated tumor in pancreatic head	Enucleation	7-mm insulinoma from pancreatic head	Cured at 3 years
5	Insulinoma	Well-defined 1.5-cm tumor midpancreatic body	1.5-cm tumor without distinct margins and extension into adjacent pancreas	Subtotal pancreatectomy splenectomy	2.0-cm insulinoma with vascular invasion and invasion into adjacent pancreas	Cured at 2 years

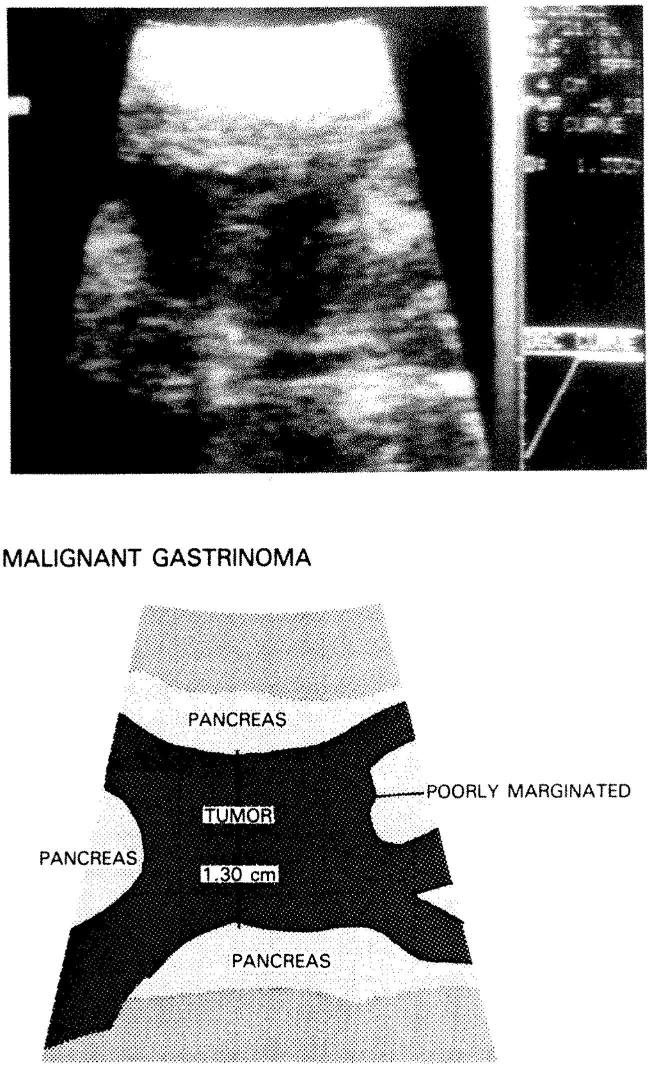

FIG. 4. Operative sonographic appearance of an islet cell tumor that was subsequently resected and proven to have malignant features pathologically. The tumor was sonolucent compared to the echogenic surrounding pancreas, but the border of the tumor was not clearly marginated and there was extension into surrounding pancreas. This sonographic appearance was consistent with a malignant islet cell neoplasm.

cell tumors not identified by palpation. A number of factors could contribute to our results. The difference in our results from those suggested in preliminary reports was unlikely to be due to a difference in expertise or the IOUS equipment used. In the present study, state-of-the-art IOUS equipment with a 10 MHz transducer was used to give the greatest possible resolution, whereas in earlier studies either 5 or 7.5 MHz[9,15] transducers were used. Although a learning curve exists for IOUS, at all operations an untrasonographer with extensive experience with ultrasound identification of islet cell tumors was present.[16] Furthermore, the sensitivity of detecting all pancreatic islet cell tumors in the present study was 93% (Table 3), which agrees closely with the sensitivity of 86% recently reported by another group with considerable expertise with IOUS localization of insulinomas.[17] It could be argued that the extensive preoperative localization studies (imaging studies, PVS), in fact, contributed disproportionally in increasing the sensitivity of palpation, which was 87% in the present study. This cannot be excluded; however, this information was available for both palpation and IOUS and should have affected the result from each procedure equally. Last, it cannot be excluded that in other centers with less experience with islet cell tumors, that IOUS may, in fact, contribute significantly more than found in the present

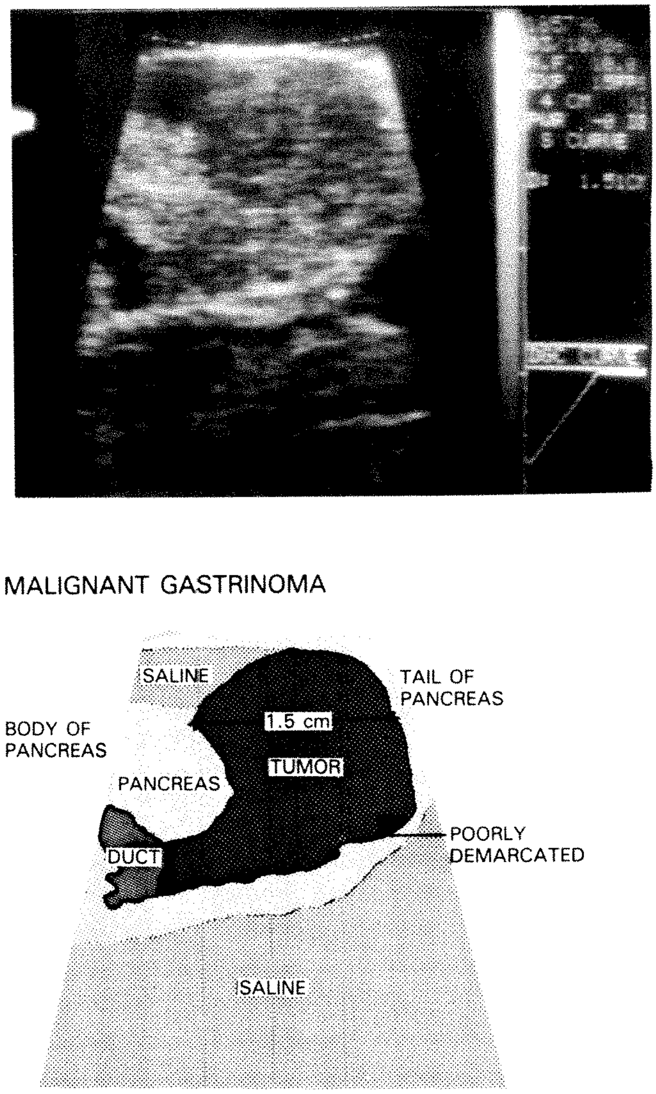

FIG. 5. Operative sonographic appearance of an islet cell tumor that was subsequently resected and proven to have malignant features pathologically. Again, the border of the pancreas and the tumor was not clearly marginated and there was total blockage of the pancreatic duct by direct invasion. This sonographic appearance was consistent with a malignant islet cell neoplasm.

study. In the present study, all patients have extensive exploration with kocherization of the duodenum, complete mobilization of the pancreatic tail, and frequently opening the duodenum even though more than one third have had previous upper abdominal surgery. This is possible because of the ability to control gastric acid hypersecretion at the time of surgery, and this allows for extensive palpation of all areas; whereas in centers with less experience, either because of adhesions from previous surgery or the inability to control hypersecretion of gastric acid, a thorough exploration may not be done, in which case IOUS may be even more valuable. Furthermore, the operating surgeon in the present study has had significant experience recognizing and palpating islet cell tumors that may have contributed to the high sensitivity of palpation.

In a technologic age, it is tempting to discount traditional operative methods like visualization and palpation in favor of expensive high technology equipment that can penetrate into structures in a noninvasive manner. However, our data clearly indicate that there are no significant differences between the two methods in detecting pancreatic islet cell tumors and that cost-effective palpation is significantly better at detecting extrapancreatic tumors. The results suggest that basic time-honored operative techniques such as palpation and visualization should not be replaced by IOUS in the search for islet cell tumors especially ones that are extrapancreatic in location. However, the results also indicate that IOUS does contribute in a fraction of patients, and in fact, is complementary to palpation.

Analysis of the false-negative and false-positive results for both palpation and IOUS provide a number of important insights. Analysis demonstrates that both the size of the islet cell tumor and location are important determinants of the false-negative rate for IOUS. Specifically, IOUS is less likely to detect an extrapancreatic gastrinoma than a pancreatic gastrinoma or insulinoma, whereas there is no difference for palpation. Furthermore, the size of gastrinomas detected with IOUS is significantly different from those not detected. Detection of sonolucent islet cell tumors by IOUS is clearer against a homogeneous echogenic background such as the pancreas than a mixed (gas-liquid-solid) background like the bowel. Small tumors (0.2–0.6 cm) in the duodenum have a higher likelihood of not being imaged, not because the 10 MHz transducer lacks resolution, but because resolution depends on the homogeneity of the background. Because in some series up to 50% of gastrinomas are extrapancreatic,[4,18,19] these results suggest that IOUS may be generally more helpful in localizing insulinomas than gastrinomas. Another difficult region to accurately image is the pancreatic tail because it is difficult to position the transducer under the left costal margin. This technical problem may be solved by mobilizing the tail of the pancreas and the spleen out of the retroperitoneum for examination, or by using a right angle high-resolution transducer (which was not available during this study). However, routine mobilization of the spleen in this manner may increase the risk of splenic injury and splenectomy. Finally, ultrasound detected some nonpalpable small false-positive images in the pancreatic head that appeared as sonolucent mass lesions similar to islet cell tumors. These lesions are normal lymph nodes within the pancreas. False-positives and false-negatives limit the present utility of IOUS and with more observer experience may be partially resolved.

A newly described advantage of IOUS is that it appears to differentiate malignant islet cell tumors from benign tumors. Benign tumors are very well demarcated with distinct hyperechoic borders (Fig. 3). Three tumors had indistinct borders, suggesting invasion into adjacent pancreas and pancreatic duct (Fig. 4 and 5), presumptive signs of malignancy. One tumor (Fig. 5) was small with ductal invasion; thus, size alone does not predict malignant potential. These tumors were resected based on IOUS results, and were found to have malignant features on pathologic analysis. Further instances and observations from other groups will be necessary to see how reliable the ultrasonic appearance of tumors predicts invasiveness and malignancy. Because up to 60–90% of gastrinomas are malignant,[12,19] whereas up to 80–90% of insulinomas are benign,[11] if, in fact, with greater experience it can be verified that IOUS can identify invasiveness, this suggests that IOUS will be more useful with gastrinomas than insulinomas to assess malignancy.

The most important consideration with any new technique is outcome. Operative sonography had clear impact on the final outcome of five patients (11%) in this study. It enabled the surgeon to find and remove two tumors that would not have been found or removed without it. It advised the surgeon to resect (instead of enucleate) three tumors with pathologic evidence of malignant invasion. All five patients in whom IOUS altered the surgical procedure are cured, albeit with short follow-up. The observation that IOUS can improve the ability of an experienced surgeon to find some nonpalpable islet cell tumors and can provide additional valuable information about invasiveness, allows us to make a strong recommendation for its use during explorations for islet cell neoplasms.

This study combined with other reports[17] indicates that IOUS is useful during abdominal explorations for pancreatic islet cell tumors. A sonolucent pancreatic mass imaged by IOUS should not be ignored because in some instances, pancreatic islet cell neoplasms will be detected that may not be palpable or visible. The appearance of islet cell tumors and their interaction with adjacent pancreas and structures can provide evidence for malignant potential and rational resection.

In conclusion, even though palpation was the single best localization method because of equal sensitivity within the pancreas and better sensitivity outside the pancreas, the present results demonstrate that, in fact, palpation and IOUS are complementary because IOUS detects some tumors that are not palpated and can provide information concerning malignant potential not detected by palpation.

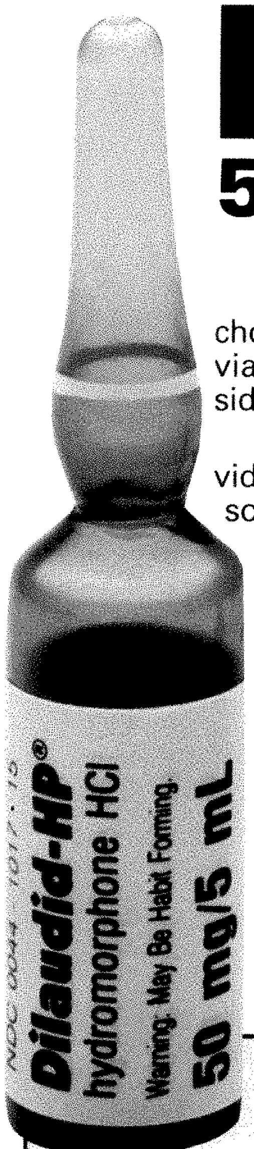
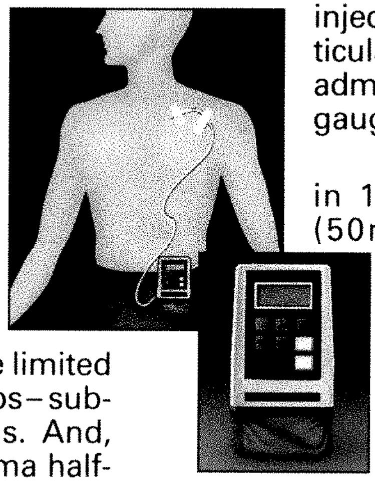
When high concentration in a limited volume is critical...



Dilaudid-HP®* ⓒII

50 mg/5 mL.

For control of severe pain, you've chosen high dose parenteral narcotics via continuous infusion. Now, consider Dilaudid HP.

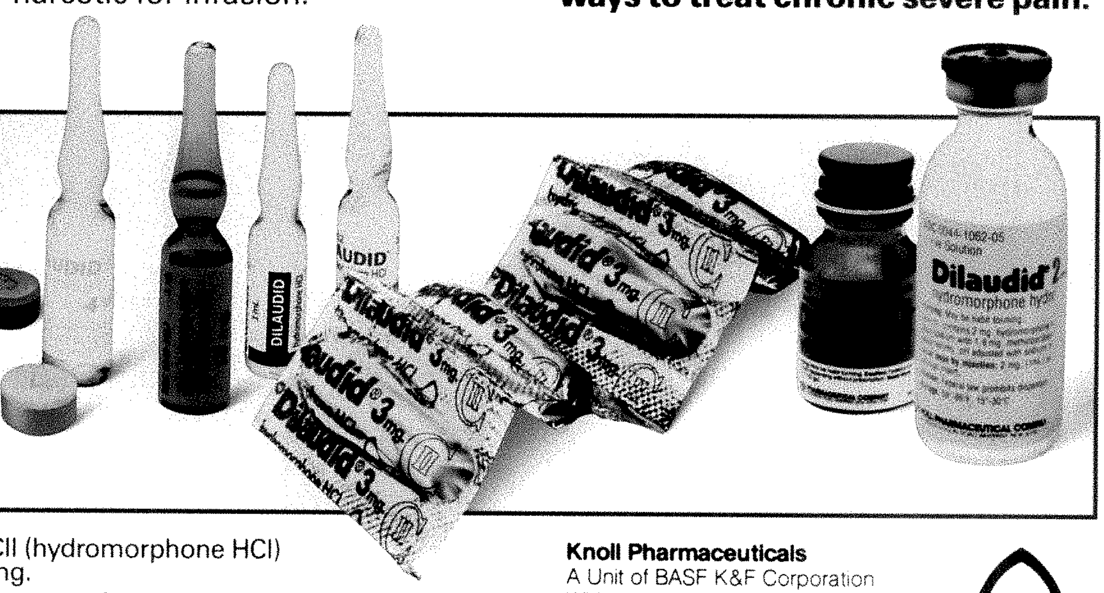


New Dilaudid HP® provides a highly concentrated solution (10mg/mL) of hydromorphone HCl. Each milligram of parenteral Dilaudid provides the analgesic equivalence of 8mg of parenteral morphine sulfate. This is vitally important given the limited volume of infusion pumps–subcutaneous or intravenous. And, Dilaudid has a short plasma half-life so essential when choosing a narcotic for infusion.

Subcutaneous injections of Dilaudid HP are well-tolerated, with minimal pain and/or burning at the injection site. And, it's particularly well accepted when administered with a short 27 gauge needle.

Dilaudid HP is available in 1mL (10mg) and 5mL (50mg) ampules–ideal potency alternatives to reduce the need for frequent changes of pump reservoirs, and reduce pharmacy time, nursing time and patient cost.

Dilaudid–Designed for the many ways to treat chronic severe pain.



*Warning: Dilaudid CII (hydromorphone HCl) may be habit forming.

Please see brief summary of prescribing information on adjacent page.

knoll®

Dilaudid-HP® ©II

hydromorphone HCl

Warning: May be habit forming

INDICATIONS AND USAGE: For the relief of moderate to severe pain.

CONTRAINDICATIONS: Hypersensitivity to hydromorphone, intracranial lesion associated with increased intracranial pressure: depressed ventilatory function (chronic obstructive pulmonary disease, cor pulmonale, emphysema, kyphoscoliosis, status asthmaticus).

WARNINGS

Drug Abuse and Dependence: DILAUDID is a Schedule C-II narcotic. Psychic dependence, physical dependence and tolerance may develop upon repeated administration of narcotics, therefore, DILAUDID should be prescribed and administered with caution.

Respiratory Depression: DILAUDID produces dose-related respiratory depression by acting directly on brain stem respiratory centers. DILAUDID also affects centers that control respiratory rhythm, and may produce irregular and periodic breathing.

Head Injury and Increased Intracranial Pressure: The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a preexisting increase in intracranial pressure. Furthermore, narcotics produce effects which may obscure the clinical course of patients with head injuries.

Acute Abdominal Conditions: Narcotics may obscure the diagnosis or clinical course of patients with acute abdominal conditions.

PRECAUTIONS

Special Risk Patients: DILAUDID should be used with caution in elderly or debilitated patients and those with impaired renal or hepatic function, hypothyroidism, Addison's disease, prostatic hypertrophy or urethral stricture.

Cough Reflex: DILAUDID suppresses the cough reflex; caution should be excercised when it is used postoperatively and in patients with pulmonary disease.

Usage in Ambulatory Patients: Narcotics may impair the mental and or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery; patients should be cautioned accordingly.

Drug Interactions: Patients receiving other narcotic analgesics, general anesthetics, phenothiazines, tranquilizers, sedative-hypnotics, tricyclic antidepressants or other CNS depressants (including alcohol) concomitantly with DILAUDID may exhibit an additive CNS depression. When such combined therapy is contemplated, the dose of one or both agents should be reduced.

Parenteral Administration: The parenteral form of DILAUDID may be given intravenously, but the injection should be given very slowly. Rapid intravenous injection increases the possibility of side effects such as hypotension and respiratory depression.

Pregnancy:*Pregnancy Category C.* Teratogenicity shown in hamsters at 600 times the human dose. There are no adequate and well-controlled studies in pregnant women. DILAUDID should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Babies born to mothers who have been taking opioids regularly prior to delivery will be physically dependent. The intensity of the syndrome does not always correlate with the duration of maternal opioid use or dose.

Labor and Delivery: Administration of DILAUDID to the mother shortly before delivery may result in some degree of respiratory depression in the newborn, especially if higher doses are used.

Nursing Mothers: It is not known whether this drug is excreted in human milk, therefore, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

FD&C Yellow No. 5: DILAUDID 1 mg. 2 mg. and 4 mg. color-coded tablets contain (tartrazine) dye which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. It is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Central Nervous System: Sedation, drowsiness, mental clouding, lethargy, impairment of mental and physical performance, anxiety, fear, dysphoria, psychic dependence, mood changes.

Gastrointestinal System: Nausea and vomiting occur infrequently; they are more frequent in ambulatory than in recumbent patients.

Cardiovascular System: Circulatory depression, peripheral circulatory collapse and cardiac arrest have occured after rapid intravenous injection. Orthostatic hypotension and fainting may occur if a patient stands up suddenly after receiving an injection of DILAUDID.

Genitourinary System: Ureteral spasm, spasm of vesical sphincters and urinary retention have been reported.

Respiratory Depression: See WARNINGS.

TRAUMA FELLOWSHIP

EASTERN VIRGINIA MEDICAL SCHOOL
DEPARTMENT OF SURGERY
DIVISION OF TRAUMA/CRITICAL CARE

The Department of Surgery of Eastern Virginia Medical School is accepting applications for a one year Trauma and Critical Care Fellowship commencing July 1, 1988. Applicants must have completed a residency program in General Surgery with education and experience in the field of Trauma/Critical Care. Applicants must be Board certified or eligible.

The fellowship will be based at Sentara Norfolk General Hospital, the designated Level I Adult/Pediatric Regional Trauma and Burn facility.

Applicants should send a letter of application, curriculum vitae and the names of three references to:

L.D. Britt, M.D., M.P.H.
Chief, Division of Trauma and Critical Care
Eastern Virginia Medical School
Medical Director, Shock Trauma Center
Sentara Norfolk General Hospital
825 Fairfax Avenue
Norfolk, VA 23507

COMPREHENSIVE AUTOLOGOUS TRANSFUSION CONFERENCE

APRIL 18 – 21, 1988

Presented by Haemonetics® Corporation, Norton Hospital, Kosair Children's Hospital, in cooperation with the University of Louisville School of Medicine.

This program is designed to offer an indepth examination of Autologous transfusion and its' relationship with the various medical disciplines. The topics will include:

- coagulation and hemostasis
- clinical immunology and hemolysis
- quality control
- equipment operation

CEU's will be offered. For further information and to receive a brochure contact:

The Effect of Somatostatin on Experimental Intestinal Obstruction

SEAN J. MULVIHILL, M.D.,* THEODORE N. PAPPAS, M.D.,‡ ERIC W. FONKALSRUD, M.D.,† and HAILE T. DEBAS, M.D.*

The effect of somatostatin (SS-14) was tested in an anesthetized rabbit model of closed-loop ileal obstruction. Experimental groups included (1) immediate treatment (N = 6) receiving SS-14 2,000 pmol × kg^{-1} × h^{-1} intravenously (I.V.) beginning at the time of ileal obstruction, (2) delayed treatment (N = 5) receiving SS-14 beginning 6 hours following ileal obstruction, and (3) control (N = 6) receiving only hydration. After 24 hours, all rabbits were killed. Significantly decreased intestinal luminal volume and sodium and potassium output was observed with both immediate and delayed SS-14 treatment when compared to control. Additionally, the gross and microscopic pathologic features of intestinal distension, inflammation, and necrosis seen in control rabbits were absent in rabbits treated with SS-14. The known broad spectrum of physiologic activity of SS-14 on the gastrointestinal tract appeared beneficial in this rabbit model of intestinal obstruction.

From the Departments of Surgery, University of California (San Francisco and Los Angeles†) and Peter Bent Brigham Hospital, Boston, Massachusetts‡*

SMALL INTESTINAL OBSTRUCTION is a common problem in surgical practice with significant morbidity and mortality rates. Historically, the recognition of hypovolemia as the major cause of death in intestinal obstruction by McCallum and others in the early 1900s, and the development of nasoenteric suction tubes for intestinal decompression by Wangensteen in the 1930s, represented major advances in the treatment of patients with intestinal obstruction. As a consequence, mortality rates decreased from 60–10% by 1955.[1] Since that time, however, few other improvements in management have occurred, and certain patients, particularly those with recurrent partial obstruction, obstruction in the early postoperative period, and obstruction associated with malignancy, present vexing clinical problems. The major morbidity rate of intestinal obstruction is still related to excessive distension leading to strangulation and bowel necrosis. There currently is no treatment directed at the known abnormal secretory patterns of the obstructed intestine.

Somatostatin (SS-14), a cyclic tetradecapeptide, was first isolated in 1973 by Brazeau et al.[2] and subsequently found to have a broad spectrum of gastrointestinal activity, including inhibition of certain hormones and inhibition of secretory and motor functions of the intestine.[3] Numerous anecdotal reports indicate that these actions of SS-14 and its analogues may be exploited to clinical advantage.[4] We hypothesized that the effects of SS-14 on intestinal ion and water transport might reduce the distension caused by mechanical obstruction.

Materials and Methods

Seventeen New Zealand rabbits (mean weight: 3.0 kg) were anesthetized with I.V. urethane (1000 mg × kg^{-1}). Hydration was maintained with I.V. infusion of Ringer's lactate (4.0 mL × kg^{-1} × h^{-1}) for the duration of the study. In each, a laparotomy was performed and a uniform 25-cm closed loop obstruction was created with ligatures in the distal ileum. This procedure had the effect of creating a simple obstruction of the proximal intestine, in addition to the ileal closed loop. Rabbits were divided randomly into three groups: (1) immediate treatment (N = 6), (2) delayed treatment (N = 5), and (3) control (N = 6). Rabbits in the immediate treatment group received SS-14 (2000 pmol × kg^{-1} × h^{-1}) in 0.1% bovine serum albumin carrier at 6.6 mL × h^{-1} I.V. beginning at the time of obstruction. Rabbits in the delayed treatment group received the same dose of SS-14 infusion but beginning 6 hours following the creation of

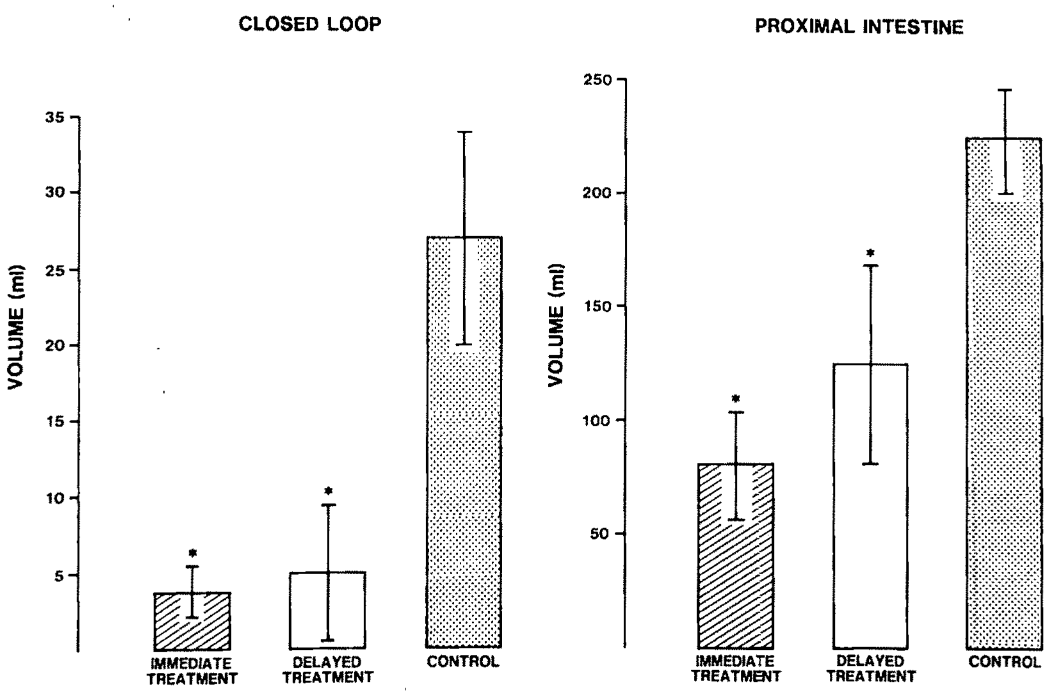

FIG. 1. Effect of immediate and delayed treatment with SS-14 of small intestinal obstruction in closed-loop and proximal segments on intestinal luminal volume. *p < 0.05 compared to control.

the obstruction. This was done to simulate the clinical situation in which patients present several hours after the onset of their obstruction. Control rabbits received the carrier alone at the same rate of infusion.

After 24 hours, the rabbits were killed with an overdose of pentobarbital, and the intestines examined. An observer who did not know to which treatment group the rabbits belonged calculated a gross pathologic score based on the presence or absence of bowel distension, edema, erythema, cyanosis, adhesions, necrosis, perforation, and free peritoneal fluid (0 = normal score; 10 = maximal score). Luminal contents of the obstructed intestine were measured and aliquots saved for analysis of sodium and potassium by flame photometry. Samples of obstructed intestine were preserved in formalin, sectioned and stained with hematoxylin and eosin, and examined microscopically for the presence or absence of inflammatory infiltrates, hemorrhage, and mucosal necrosis. With these criteria, a microscopic pathology score was assigned (0 = normal score; 3 = maximal score).

SS-14 (Sigma Chemical Company, St. Louis) was mixed freshly from the powder in carrier solution for each experiment. The infusate solutions were kept on ice and infused by Harvard peristaltic pumps at a constant rate. No rabbits vomited, and all survived the 24-hour study period. Since the animals were kept anesthetized for the entire 24-hour period, they experienced no pain. This study was performed in accordance with the guidelines of the National Research Council for the care and use of laboratory animals.

Statistical analysis was performed utilizing Student's t-test for unpaired values. A p value of less than 0.05 was considered significant. Throughout, the data is given as mean ± SEM.

Results

SS-14 treatment had a profound effect on luminal volume in the obstructed small intestine, both in the closed loop and in the proximal portions. Control rabbits had a mean luminal volume of 26.9 ± 7.0 mL in the closed-loop segment, whereas rabbits receiving immediate SS-14 treatment had only 3.7 ± 1.7 mL, representing a sevenfold reduction in fluid volume. Rabbits receiving delayed treatment with SS-14 had a mean luminal volume of 4.9 ± 4.8 mL. In the small intestine proximal to the closed-loop segment, significant reductions in luminal volume were also seen with immediate and delayed SS-14 treatment (224 ± 22 mL control *vs.* 80 ± 24 mL immediate treatment and 124 ± 43 mL delayed treatment). These data are summarized in Figure 1.

Although luminal sodium concentration was unchanged in the treated and in the control groups (148 ± 4 mmol $\times$ L^{-1} *vs.* 147 ± 5 mmol $\times$ L^{-1}), there was a significant reduction in luminal sodium output in both the immediate and the delayed treatment groups when compared to control (Fig. 2). Mean luminal sodium output in the closed-loop segments was 3.8 ± 0.1 mmol in the control group compared with 0.5 ± 0.2 mmol in the immediate treatment group and 0.8 ± 0.8 mmol in the delayed treatment group. Similarly, significant re-

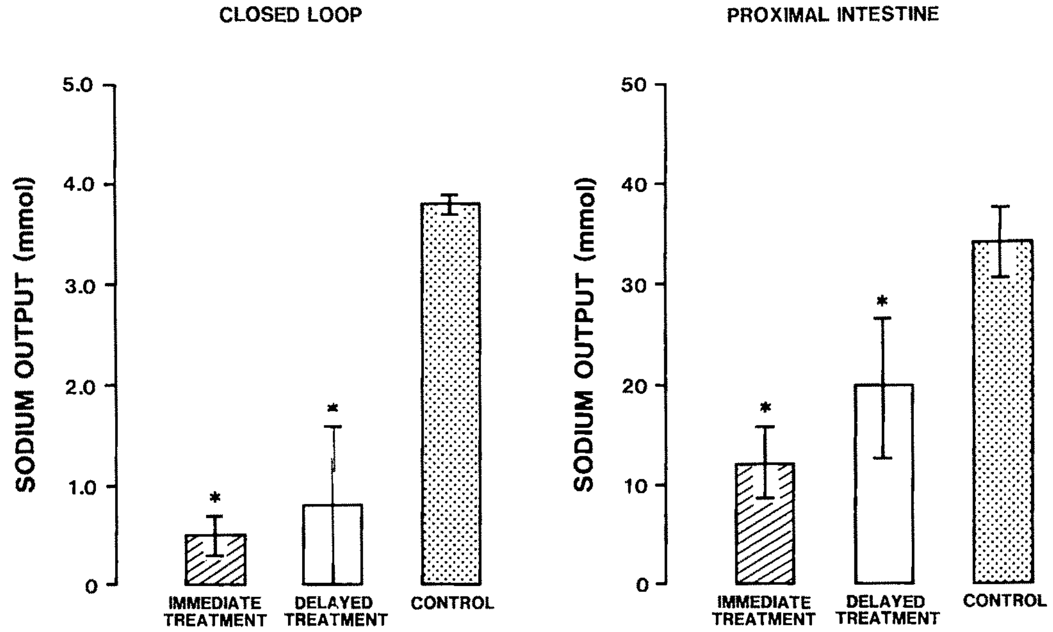

FIG. 2. Luminal sodium output in obstructed rabbit small intestine with and without treatment with SS-14. *p < 0.05 compared to control.

ductions in luminal sodium output occurred in the intestine proximal to the closed-loop segments with SS-14 treatment (33.9 ± 3.5 mmol control *vs.* 12.2 ± 3.6 mmol immediate treatment and 19.7 ± 7.1 mmol delayed treatment).

SS-14 treatment resulted in significantly increased luminal potassium concentration but decreased potassium output in the proximal obstructed intestine (Table 1). In the closed-loop segments, there were no significant differences in luminal potassium concentration. SS-14 treatment, however, resulted in significant decreases in luminal potassium output in both the immediate and delayed treatment groups when compared to control.

SS-14 treatment also resulted in dramatic differences in the gross appearance of the obstructed intestine compared to control. In the closed-loop segments, control rabbits had a mean gross pathologic score of 5.3 ± 1.3, with three rabbits having localized areas of necrosis. Closed-loop segments in rabbits treated with SS-14 had essentially none of the aforementioned changes, with mean scores of 0.3 ± 0.2 (immediate treatment) and 0.6 ± 0.6 (delayed treatment). Although the proximal intestine was not as severely affected as the closed-loop segments in control rabbits (mean score: 3.8 ± 0.9), significant improvements were still observed with SS-14 treatment (immediate treatment: 0.7 ± 0.2; delayed treatment: 1.2 ± 0.5). These data are shown in Figure 3.

At microscopic examination, the above gross findings were confirmed in the closed-loop segments. Figure 4 depicts the microscopic pathologic scores from closed-loop segments in control rabbits (2.3 ± 0.3) compared to immediate treatment (0.3 ± 0.2) and delayed treatment (0.4 ± 0.2) rabbits. Extensive mucosal necrosis and intramural hemorrhage and inflammatory infiltrates were seen in closed-loop segments from control rabbits, findings that were absent in the group treated with SS-14. Representative sections are shown for comparison in Figure 5. No significant histopathologic changes were seen in the proximal intestine in any of the groups.

Discussion

In the face of unremitting mechanical obstruction, progressive intestinal distension leads to vascular com-

promise, ischemia, and necrosis. At least three factors contribute to intestinal distension in this situation: (1) accumulation of gastric, pancreatic, and biliary secretions; (2) decreased absorption of water and sodium from the intestinal lumen; and (3) increased secretion of water and sodium into the lumen of the distended segment. Shields[5] described an *in vivo* model of ileal obstruction in dogs. He found decreased absorption of water and sodium in the obstructed segments followed by increased secretion of water and sodium intraluminally as distension increased. These findings were confirmed by Wright et al.[6] who produced temporary ileal obstruction with balloons in humans with ileostomies. A vicious cycle of decreased absorption and increased secretion occurs in distended, obstructed ileal segments.

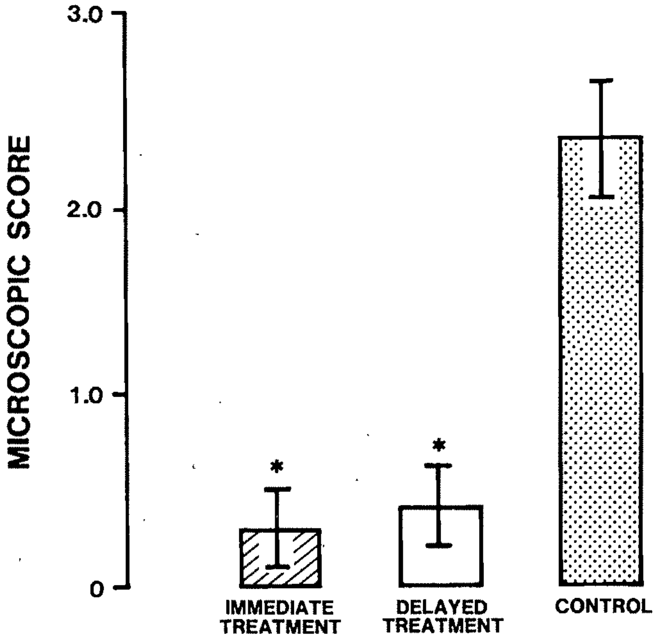

FIG. 4. Microscopic pathologic score from ileum with closed-loop obstruction with and without SS-14 treatment. $*p < 0.05$ compared to control.

SS-14 has been shown *in vitro* to increase water and electrolyte absorption in rabbit ileum[7,8] and to inhibit water secretion in rat jejunum.[9] Additionally, numerous studies have demonstrated inhibition of gastric, biliary, and pancreatic secretion by SS-14.[3,10] These studies, as well as several clinical reports of control of secretory diarrhea by SS-14,[11,12] led us to test the efficacy of SS-14 in the management of the intestinal secretory disturbances caused by mechanical small bowel obstruction.

In our study, uniform closed-loop obstructed ileal segments were created, resulting additionally in proximal simple obstructions in anesthetized rabbits. All rabbits were maintained with intravenous hydration, and all survived the 24-hour study period. Intestinal obstruction in these rabbits led to marked distension, cyanosis, and patchy necrosis, particularly in the closed-loop segments. These findings were prevented by SS-14 treatment, even when onset of treatment was delayed for 6 hours after obstruction. In addition to the marked decreases in intestinal luminal volume seen in treated rabbits, significant reductions in sodium and potassium output were present, implying inhibition of water, sodium, and potassium secretion in the obstructed intestine by SS-14. Alternatively, the effects noted could have been due to enhanced absorption by SS-14 of water and

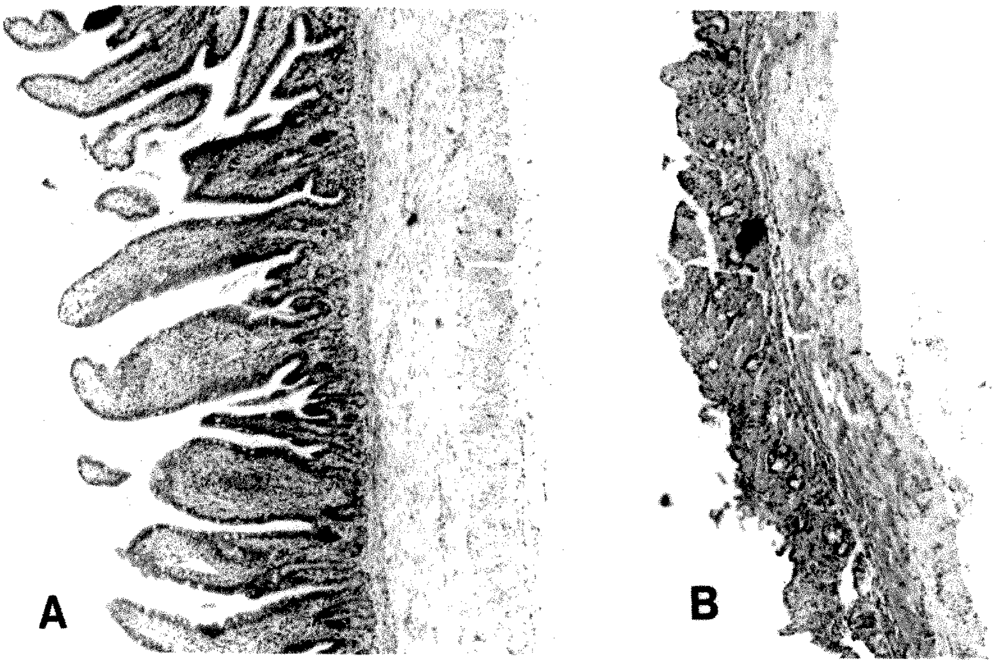

FIG. 5. Representative microscopic sections stained with hematoxylin and eosin from rabbit ileum with closed-loop obstruction (original magnification ×40). *A*. SS-14 treatment. *B*. Control.

electrolytes from the obstructed bowel. The present study was not designed to examine in detail the mechanisms involved in the protection afforded by somatostatin. It is possible mechanisms other than prevention of distension by luminal fluid also operate when somatostatin is employed. For example, with ischemia powerful vasoactive substances [*e.g.*, vasoactive intestinal peptide (VIP)] are released locally in the gut wall.[13] Somatostatin may inhibit release of such agents and protect microcirculation failure and edema and hemorrhage in the bowel wall. Future studies will be designed to examine the protective mechanisms of somatostatin in small bowel obstruction.

It is clear that SS-14 treatment cannot correct the underlying pathology when complete mechanical small bowel obstruction exists. However, the ability to prevent further distension by pharmacologic inhibition of gastrointestinal, biliary, and pancreatic secretion may be of value as an adjunct to I.V. fluid repletion and diagnostic studies in patients with complete small bowel obstruction. Additionally, and perhaps more importantly, such pharmacologic manipulation may aid management of patients with partial small bowel obstruction, the vast majority of whom do not require operative treatment. Additionally, patients with obstruction related to malignancy and obstruction in the early postoperative period, both settings where nonoperative management is preferable, may benefit from pharmacologic reduction of intestinal luminal volume. We believe additional animal studies and subsequent controlled clinical trials are necessary before somatostatin can be used as a clinical adjunct in the treatment of small bowel obstruction.

Colonoscopic Detection of Early Colorectal Cancers

Impact of a Surgical Endoscopy Service

WALTER E. LONGO, M.D., GARTH H. BALLANTYNE, M.D., and IRVIN M. MODLIN, M.D.

The Surgical Endoscopy Service has been aggressively evaluating gastrointestinal symptoms with colonoscopy and screening asymptomatic patients with flexible sigmoidoscopy in hopes of finding early curable colorectal cancers. The purpose of this study was to compare the stages of colorectal cancers resected during the 18-month period prior to (Pre-SES) and during the first 18 months (Post-SES) after the creation of the Surgical Endoscopy Service. In addition, the yield of lesions that would have been obtained by depending upon patient symptoms or occult blood testing were determined. A total of 361 colonoscopies were performed Pre-SES and 874 colonoscopies Post-SES; 26 patients underwent resection of colorectal cancers Pre-SES and 32 Post-SES. Whereas early colorectal cancers (Dukes' A and B_1) were found in only three patients (12%) Pre-SES period, early cancers were found in 13 (41%) Post-SES. Doubling the number of colonoscopies produced a fourfold increase in the number of early lesions. Furthermore, disseminated cancers (D lesions) dropped from 19% Pre-SES to 3% Post-SES. Among the total 58 patients, 43% of the A lesions and 40% of the B_1 lesions were asymptomatic. Even more alarming, 86% of the A lesions, 50% of the B_1 lesions, 31% of the B_2 lesions, and 14% of the C_2 lesions were occult blood negative. Indeed, only the D lesions were uniformly occult blood positive. This study demonstrates that aggressive colonoscopy detects early colorectal cancers. Moreover, patient symptoms or occult blood testing will fail to indicate the majority of early colorectal cancers.

Department of Surgery, Yale University School of Medicine,
and the West Haven VA Medical Center,
West Haven, Connecticut

THERE ARE MORE THAN 130,000 new cases of colorectal cancer each year in the United States.[1] Despite this rising incidence, few advances in the treatment of colorectal cancer have been achieved. Indeed, survival of patients with colorectal cancers has not significantly changed in the last three decades.[2] Furthermore, adjuvant chemotherapy, radiotherapy, or immunotherapy have not altered at all treatment results of patients with colorectal cancers.[3] Little hope exists, therefore, of improving therapeutic results in patients with colorectal cancer. Consequently, an alternative strategy must be pursued if the death rate from colorectal cancer is to be diminished.

Results of treating early colorectal cancer are excellent. Sir Edward Hughes reported an 80% survival rate in treating patients with Dukes' A lesions (*i.e.*, lesions limited to the bowel wall without lymph node involvement).[4] Turnbull reported a 98% 5-year survival rate for 103 patients with Dukes' A lesions.[5] These results would suggest that the best hope of improving survival rates of patients with colorectal cancer lies in finding these cancers while they remain confined to the bowel wall rather than striving for new modalities for treating advanced or disseminated disease.

Much effort has been invested in evaluating various methods for screening large populations for colorectal cancer. Testing stool for occult blood has been an attractive technique for performing screening tests for several reasons; the tests are inexpensive, easy to perform, and the results are easy to interpret. Unfortunately, no study that has tested a population for occult blood in stool has succeeded in decreasing colon cancer-related deaths in that population.[6-10]

Proctosigmoidoscopy is an effective means of detecting rectal cancers.[11] In a large prospective study at the University of Minnesota, Gilbertson succeeded in nearly obviating the occurrence of rectal cancer in a population of patients that he routinely screened with a rigid proctosigmoidoscope.[12] Unfortunately, the percentage of colorectal cancers now within the reach of the rigid scope is rapidly dropping. Greene found only 26% of colorectal cancers in the rectum and only another

Submitted for publication: August 14, 1987.

28% throughout the sigmoid colon.[13] It would seem from these studies that endoscopic evaluation of the colon and rectum is the best means of identifying colorectal cancers and that flexible endoscopic instruments are necessary for reaching the majority of these lesion.

The purpose of this study was to determine the effect of the surgical endoscopy service on the stage of colorectal cancer surgically treated in our institution. Specifically, we established the number of colonoscopies performed in the West Haven Veterans Administration Hospital during the 18 months prior to the onset of the surgical endoscopy service and during the subsequent 18 months. In addition, we compared the stage of each colorectal cancer treated during these two time periods. Furthermore, we contrasted the yield of early colorectal cancers obtained by endoscopic evaluation of the colon with that obtained from a careful history and that from testing the stool for occult blood. The results of this study suggest that aggressive colonoscopy is the best means for uncovering early curable colorectal cancers.

Materials and Methods

We retrospectively reviewed the charts of all patients surgically treated for colorectal cancers at the West Haven Veterans Administration Medical Center during a 36-month period. One group of patients was identified during the 18-month time frame from April 1, 1983 to September 30, 1984. This was deemed the Pre-Surgical Endoscopy Service (Pre-SES) time period. The second group of patients was treated during the first 18-month period after the onset of the surgical endoscopy service: October 1, 1984 to March 31, 1986. This was deemed the Post-Surgical Endoscopy Service (Post-SES) time period.

Data was extracted from the hospital charts of the patients. The patients' age, sex, chief complaint, indication for evaluation, and stool occult blood status were culled from the chart. Occult blood tests were performed on fresh stool specimens obtained by physicians during physical examinations. No patient was placed on special diets before stool occult blood testing, and samples were not rehydrated before testing. For most patients, more than one stool occult blood test was available. The patient was judged occult blood positive if any one stool occult blood test was positive or trace positive. Endoscopy reports and operative notes were reviewed to determine the position of the lesion and the extent of disease. Pathology reports were reviewed to determine the depth of bowel wall penetration of the lesion and for the presence of lymph node metastases. If the pathology report was ambiguous about the depth of penetration, the original pathology slides were reviewed. Based on this information, each lesion was staged by the Astler-Coller modification[14] of the Dukes'[15] classification for carcinoma of the colon and rectum (Table 1). In addition, a D stage was included as suggested by Turnbull.[16] All data were entered into a computerized data base system (Symphony, Lotus Development Corporation, Cambridge, MA) for analysis. Results were tabulated for each time period, Pre-SES and Post-SES. In addition, the data were compiled for the entire 36-month time period. Results were expressed as mean and SEM. When groups were compared, significance was judged as $p < 0.05$) using Student's t-test for unpaired samples.

TABLE 1. *Modified Dukes' Classification of Astler and Coller with Addition of a D Category*[14-16]

Stage	Definition
A	Limited to mucosa
B_1	Invasion of muscularis mucosa, submucosa, or musularis propria
B_2	Complete penetration of muscularis propria
C_1	Invasion of muscularis mucosa; lymph nodes involved
C_2	Complete penetration of muscularis propria; lymph node involved
D	Distant metastases

Results

There were 58 patients found to be eligible for the study, 26 in the Pre-SES period, and 32 patients during the Post-SES period. The age of the patients in both groups was similar; the average in the Pre-SES group A was 66.2 years ± 2.2 and in the Post-SES group 66.6 years ± 2.0. All patients in both groups were men.

The chief complaints for these 56 patients are listed in Table 2. Only 7.7% of Pre-SES patients were without symptoms when their colorectal carcinoma was discovered. In contrast, 28.1% of Post-SES patients were asymptomatic. The distribution of other chief complaints was otherwise similar between the two groups.

The duration of symptoms prior to seeking medical attention is listed in Table 3 for both groups. The aver-

age duration of symptoms for Pre-SES patients (3.9 ± 0.6 months) and for Post-SES patients (2.9 ± 0.6 months) were not significantly different ($p > 0.05$).

Pre-SES patients had a greater percentage of left-sided lesions than Post-SES patients (Table 4). In the Pre-SES group, 9 of 26 (34.6%) lesions were in the cecum, ascending colon, hepatic flexure, or transverse colon. In the Post-SES group, 14 of 32 (43.8%) lesions were in these locations. The greater number of cecal lesions in Post-SES group accounts for this greater proportion of right-sided lesions.

Total	26	100	32	100

Patients Pre-SES tended to have more advanced lesions at the time of treatment (Table 5). Among Pre-SES patients, only three patients had early lesions (11.5%); one patient (3.8%) had a Dukes' A lesion, and two patients (7.7%) a Dukes' B_1 lesion. In sharp contrast, 14 Post-SES patients (43.8%) had early lesions; 6 with Dukes' A lesions (18.8%), and 8 with Dukes' B_1 lesions (25.0%). This represents a nearly fourfold increase in the number of early colorectal cancers. In addition, there was a marked decline in the number of Dukes' D lesions in Post-SES patients as compared to Pre-SES patients—5 of 26 (19.2%) lesions Pre-SES *versus* 1 of 32 lesions (3.1%) Post-SES.

The number of patients who were asymptomatic at the time that their colorectal cancer was diagnosed is listed in Table 6. Whereas symptoms were absent in more than 40% of patients with A or B_1 lesions, symptoms were present in more than 90% of patients with advanced lesions. Overall, only 19% of patients were asymptomatic at the time of diagnosis.

Occult blood testing poorly detected early colorectal cancers. Although overall 16 of 58 patients (73%) were occult blood positive, 11 of 17 patients (65%) with early colorectal cancers were occult blood negative. Figure 1 demonstrates the per cent of patients that were occult blood negative for each stage of cancer. Of particular importance is the fact that 86% of patients with Dukes' A lesions and 50% of patients with Dukes' B_1 lesions were occult blood negative.

Discussion

In this study we have compared the number of colonoscopies performed and the stages of colorectal cancer treated in our hospital during two consecutive time periods: Pre-SES and Post-SES. The number of colonoscopies more than doubled from the first time period to the second. A dramatic shift in stage of colorectal cancers was also demonstrated from the first period to the second. In fact, doubling the number of colonoscopies from the first period to the second resulted in uncovering a fourfold increase in the number of early colorectal cancers (Dukes' A and B_1 lesions). This study demonstrates the ability of aggressive colonoscopy to increase the detection rate of early colorectal cancers.

This study has also demonstrated that traditional means of detecting colorectal cancers fail to detect early lesions. Among the 58 patients treated during the 36-month study period, 43% of patients with A lesions and

40% of patients with B_1 lesions complained of no symptoms. Thus, history alone would have missed 41% of early (Dukes' A and B_1 lesions) colorectal cancers. Once a patient develops symptoms from his colorectal malignancy, the lesion is generally advanced or, indeed, disseminated.

Additionally, this study has demonstrated that occult blood testing fails to detect early colorectal cancer. Among these patients, 86% of A lesions and 50% of B_1 lesions were occult blood negative. Consequently, 65% of early colorectal cancers in our patients were not detected by the occult blood test. These data indicate that under most circumstances, only advanced or disseminated colorectal cancers produce symptoms or loose blood into the stool.

In our study, the occult blood test was falsely negative in 27.6% of all patients with colorectal cancers. This is consistent with other studies. Wexner et al.[17] reported that the occult blood test was negative in 44% of 100 patients with colorectal cancers. Crowley et al.[18] reported the occult blood test was positive in only 52% of 213 patients with colorectal cancers. Recent reviews estimated the false-negative rate for occult blood testing in patients with colorectal cancers as between 40% and 60%.[9,19,20]

Occult blood testing poorly detects right-sided carcinomas. In the Nottingham study only one carcinoma was detected beyond the splenic flexure in 3613 patients who underwent fecal blood testing.[21] In the University of Minnesota study, 38 carcinomas were detected beyond the splenic flexure in 48,000 patients.[22] At the Hines VA, four carcinomas were detected beyond the splenic flexure in 2964 patients.[23] In Erie County, New York, two proximal colon carcinomas were detected among 3822 patients.[7] In these four studies then, 8.3% of the Nottingham carcinomas, 33.6% of the Minnesota carcinomas, and 28.5% of the Hines carcinomas and 28.6% of the Erie County carcinomas were beyond the splenic flexure. This low yield of carcinomas from beyond the splenic flexure is consistent with the yield of proximal carcinomas in our Pre-SES period (34.6%). The higher percent of proximal carcinomas in our Post-SES period (43.8%) and the results of other studies,[13] however, suggest that occult blood testing failed to detect a substantial number of proximal colorectal cancers.

The best means of performing the occult blood test remains ill defined. In our study, patients were not given any dietary restrictions, the stool smear was not rehydrated before development, and no specific number of occult blood tests were performed though several were generally obtained. If any one test was positive, the patient was counted as being occult blood positive. Some consider special diets for 3 days prior to testing as an integral part of occult blood testing.[7] Many components of a normal diet may cause a falsely positive occult blood test. Several of these include radishes, broccoli, cantaloupe, turnips, bean sprouts, cauliflower, red meats, and iron.[19] Others state that dietary restrictions only decrease the specificity of the test.[24] Similarly, no uniformity of opinion exists as to the best number of stool samples that should be tested. Greegor[25] initially suggested testing six stool smears from three different bowel movements. Macrae has pointed out that increasing the number of tests increases the sensitivity of occult blood testing but diminishes the specificity.[24] Other techniques that serve to increase the sensitivity of occult blood testing, such as rehydrating the smeared stool sample before applying the developing solution, also decrease the specificity.[10] Unfortunately, it remains true that no prospective trial has compared these variables in a controlled fashion and, thus, the best means of administering the stool occult blood test remains uncertain.

TABLE 6. *The Number of Patients with Occult Blood Absent (−) in Their Stools and the % Without Symptoms are Listed for 58 Patients Treated at the West Haven VA Medical Center During the 36-Month Study Period*

	Occult Blood −		Asymptomatic

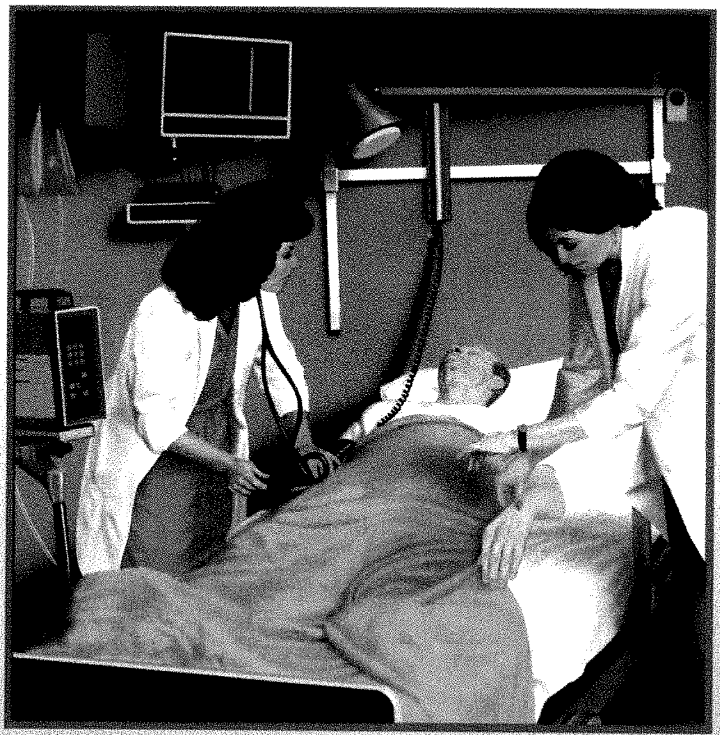
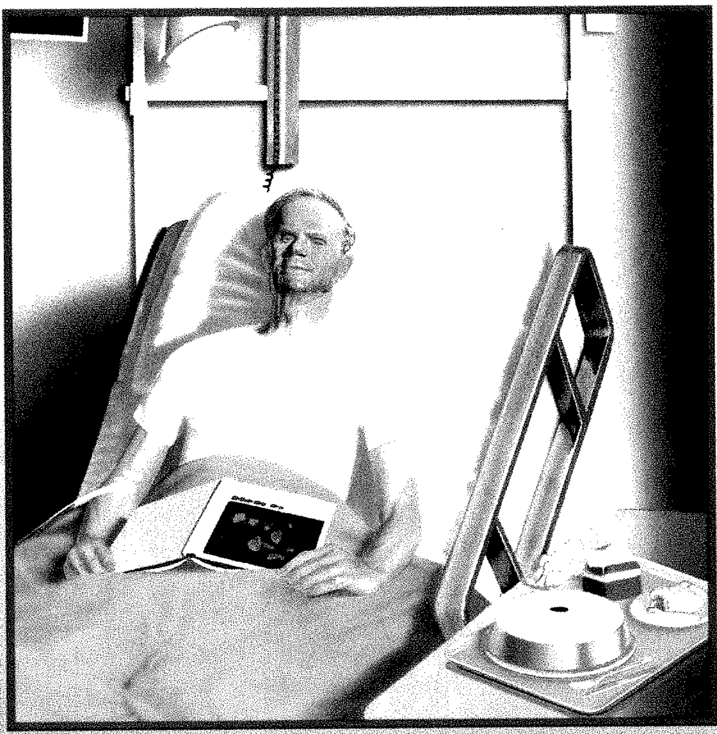
INFECTION IN THE ELDERLY PATIENT



"NEPHROTOXICITY LIMITS THE CLINICAL UTILITY OF AMINOGLYCOSIDES."[1]

AZACTAM®
AZTREONAM



IN ELDERLY PATIENTS—GRAM-NEGATIVE EFFICACY WITHOUT AMINOGLYCOSIDE TOXICITY

AZACTAM®
AZTREONAM
FOR INJECTION

CLINICAL EFFICACY PROVEN IN STUDIES WITH NEARLY 300 ELDERLY PATIENTS[2-9]

- Efficacy comparable to aminoglycosides, with excellent activity against a wide range of susceptible gram-negative aerobic organisms, including *Pseudomonas aeruginosa*[2-4]

SUPERIOR SAFETY PROFILE[*2,3,10]—
ESPECIALLY IMPORTANT IN ELDERLY PATIENTS

- Does not cause nephrotoxicity[†10-13]
- Does not cause ototoxicity[10,11]
- Requires no costly routine blood monitoring[‡]
- Avoids the costs that nephrotoxicity adds to all patients on aminoglycoside therapy (average $183/patient)[14]

[*] Dosage adjustment, based on estimated creatinine clearance, may be necessary in elderly patients.

For a discussion of INDICATIONS AND USAGE (including susceptible organisms), CONTRAINDICATIONS, PRECAUTIONS, and ADVERSE REACTIONS, please consult brief summary on adjacent page.

[†] Demonstrated in animal studies, and in human volunteer studies involving 36 subjects. In clinical trials involving 4,570 subjects, transient elevations in serum creatinine were rarely observed.

[‡] Renal function should be monitored when AZACTAM (aztreonam) is used concomitantly with aminoglycosides. In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy.

INSTEAD OF AMINOGLYCOSIDES...
ESPECIALLY IN ELDERLY PATIENTS

ACT AZACTAM®
AZTREONAM

AZACTAM® FOR INJECTION

Aztreonam For Injection

DESCRIPTION—AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile nonpyrogenic white powder, containing approximately 780 mg L-arginine per gram of aztreonam, for intramuscular or intravenous use following constitution. The powder is sodium-free. Aqueous solutions of aztreonam have a pH in the range of 4.5 to 7.5.

INDICATIONS AND USAGE—Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca**, *Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis**, *Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae**, *Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae**, *Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy—Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS—Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS—Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS—General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy—Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers—Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use—Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS—Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity: *Hypersensitivity*—anaphylaxis. *Hematologic*—pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*—abdominal cramps; rare cases of *C. difficile*-associated diarrhea or gastrointestinal bleeding have been reported. *Dermatologic*—purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*—hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*—one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*—hepatitis, jaundice. *Nervous System*—seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*—muscular aches. *Special Senses*—tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*—vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*—weakness, headache, fever, malaise.

Adverse Laboratory Changes—Those reported without regard to drug relationship during clinical trials were: *Hepatic*—elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*—increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*—increases in serum creatinine.

OVERDOSAGE—If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION—Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED—AZACTAM For Injection (Aztreonam For Injection) is supplied in single-dose 15 mL vials containing **500 mg, 1 g** or **2 g** per vial, and in single-dose 100 mL intravenous infusion bottles containing **500 mg, 1 g** or **2 g** per bottle.

Consult package insert before prescribing AZACTAM (aztreonam).

Epidural spinal cord electrical stimulation (ESES) was performed on 10 patients with severe limb ischemia due to atherosclerotic disease. Microcirculatory parameters were assessed before and after ESES. Bright field microscopy was used to assess capillary diameters and red blood cell (RBC) velocity in the dorsum of the foot. Fluorescein microscopy was used with intravenously injected sodium fluorescein to study capillary density and sodium fluorescein appearance time in the dorsum of the toe. The systolic ankle/arm pressure ratio and toe pressure measurements were used as macrocirculatory parameters. After ESES, clinical improvement was confirmed by intravital microscopy. Capillary density increased ($p < 0.001$), RBC velocity in capillaries already perfused before ESES increased from 0.054 mm/sec to 0.762 mm/sec ($p < 0.001$), and sodium fluorescein appearance time decreased from 72 to 45 seconds ($p < 0.001$). Capillary diameter did not change significantly so that the increase in RBC velocity may be interpreted as enhanced volume flow. Systolic ankle/arm pressure ratios and digital arterial pressure did not change significantly. The current results show that in patients with severe occlusive arterial disease of the lower limbs, ESES recruits capillaries not perfused in the control situation and enhances skin blood flow, improvements that may explain the beneficial clinical effects of ESES.

THE SYMPTOMS OF atherosclerotic occlusive arterial disease of the lower limb include intermittent claudication at a relatively early stage of the disease, followed by ischemic rest pain, ulceration, and gangrene as the disease progresses. Vascular surgery is the therapy of choice, but in approximately 20% of the patients with stage IV disease, according to Fontaine, reconstructive surgery is not effective anymore.[1] In these patients, lumbar sympathectomy[2] and conservative treatment[3] generally fail to improve blood supply to the limb and amputation is the last alternative treatment.[3]

Epidural spinal electrical stimulation (ESES) is a medically accepted therapeutic modality for the control of chronic pain. The best results with ESES have been obtained in patients with intractable low back pain, causalgia, and phantom limb pain.[4] Recently, spinal cord stimulation was also successfully used in patients with ischemic rest pain. Strikingly enough, not only pain relief was achieved, but also healing of ischemic ulcers occurred,[5] suggesting that ESES improves nutritional blood flow. Attempts have been made to delineate these beneficial, clinical effects with the use of the xenon washout technique,[6] ankle pressure measurements,[7,8] or photoplethysmography.[9,10] These macrocirculatory techniques, however, are not sensitive enough to evaluate the effect of ESES on the microcirculatory disturbances, occurring in patients with ulcers and gangrene. In these patients, evaluation of treatment should ideally take place at the level at which the ischemic phenomena occur: the skin nutritional capillaries. Intravital capillary microscopy is a noninvasive method to study the morphologic pattern of the microcirculation[11] and allows the measurement of red blood cell velocity in the skin capillaries, which specifically reflects nutritional blood flow.[12] This technique enables objective evaluation of treatment and can even discriminate respondents from nonrespondents to treatment.[13]

The aim of this study was to evaluate the effects of ESES on microcirculatory blood flow. Morphologic and dynamic capillary microscopy was performed before and after ESES in 10 patients with severe lower limb ischemia.

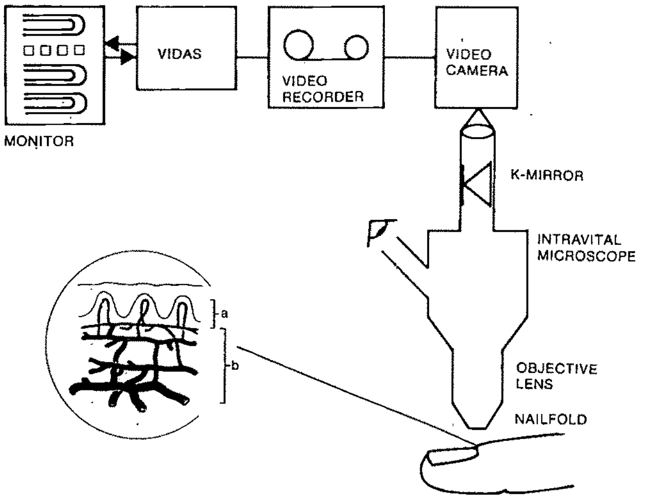

FIG. 1. Schematic representation of the set up for capillaroscopy and of the skin vascular bed, showing the nutritional (a) and thermoregulatory (b) part of skin blood supply.

Patients and Methods

Patients

ESES was performed on 10 patients with occlusive arterial disease of the lower limbs due to atherosclerosis, combined with diabetes in four patients. The mean age of these eight men and two women was 77 years (range: 72–84 years).

Before ESES, patients had vascular reconstructive surgery or sympathectomy without satisfactory result. Angiography, either monoplanar translumbar aortography or biplane selective femoral punction arteriography, showed occluded crural arteries technically unsuitable for reconstructive surgery. Conservative treatment and vasodilating drugs were not effective. All patients had intolerable unilateral rest pain and eight of them had nonhealing ischemic ulcers. The only possible therapeutic alternative was limb amputation.

Protocol

The first patient was treated with ESES 15 months ago; the last patient was treated 2 months ago. Because of the short follow-up period, only the acute effects of ESES on vascular blood flow are presented. The following macro- and microcirculatory parameters were investigated 1 day before and 1 day after ESES.

Macrocirculation

The systolic ankle/arm pressure index, expressed as a percentage, was determined by dividing the systolic pressure, as measured over the posterior tibial or the dorsal pedal artery, by the systolic brachial artery pressure and multiplying this ratio by 100%. The pressure measurements were made with a bidirectional continuous wave Doppler instrument with a zero-crossing circuitry.

Photoplethysmography was used to measure the systolic pressure in the digital arterial system of the toe, using a pressure cuff around the proximal phalanx with a width of 1.5 cm. The systolic pressure was expressed in mmHg.

Microcirculation

Nutritional capillary blood flow and capillary morphology were studied by means of intravital microscopy with objectives L4× (numerical aperture NA = 0.04) and L10× (NA = 0.22). Figure 1 schematically represents the set up with a magnification of the skin microcirculation: arterioles and arteriovenous anastomoses, which form the thermoregulatory part of skin blood flow, and skin capillaries, which are responsible for the nutritional part of skin blood flow. The foot of the sitting patient was positioned on the stage of the microscope and fixed in a mass of clay. A drop of paraffin oil was applied to the nailfold and skin to minimize reflections. The technique of capillary microscopy has been described in detail before.[14,15] Essentially, the system (Fig. 1) consists of the microscope, which is connected with a television monitor through a low light level television camera. For offline analysis the images were stored on a videotape recorder. Capillaries were randomly chosen in the nailfold and dorsum of the skin of the foot to determine the following morphologic and dynamic parameters: (1) the density of the capillary loops, as measured with objective 4×. The density was expressed as the number of capillary loops per square millimeter. (2) The diameter of the capillary loop, using the objective 10×. Diameters were expressed in micrometers. (3) Capillary red blood cell (RBC) velocity, as measured with a video flying spot method.[16] In this technique, a spot moving over the videoscreen is synchronized with the moving red blood cells or plasma gaps. The advantage of this system is that very low RBC velocities can be measured accurately. (4) Appearance time of intravenously injected sodium fluorescein and number of capillaries perfused with this dye. Two milliliters of 10% sodium-fluorescein were injected intravenously, where on the arrival of the dye in the skin of the foot, was assessed with the use of a fluorescein microscope filter. The time between injection of the dye and arrival in the foot was defined as the appearance time, expressed in seconds. Furthermore, the number of capillaries filled with sodium-fluorescein was determined and expressed in number per square millimeter. Since sodium-fluorescein binds to plasma proteins, these capillaries filled with sodium-fluorescein do not only represent blood perfused capillaries, but also the capillaries perfused with plasma.

Surgical Procedure

Under local anesthesia, a vertical incision parallel to the spinal column was made. Through a Tuohy needle, an electrode was introduced into the epidural space at the level of L3–L4 and placed in the midline approximately at the level of T10. This was performed under x-ray control. The lead was manipulated until the patients experienced pleasant paresthesias extending down into both legs. Patients were stimulated either by external stimulation or by an internal device that was implanted in a subcutaneous pouch connected to the epidural electrode via a subcutaneous extension (Medtronic Inc., Minneapolis, MN).

Bipolar stimulation was performed with a pulse width of 0.2 msec and a frequency of 120 Hz. The amplitude varied between 4 and 9 V, depending on the patient's subjective feeling of comfortable paresthesias.

Statistical Analysis

In the tables, the data are presented as mean values and standard deviations. The Student's t-test was applied to evaluate the differences before and after ESES.

Results

Subjective Findings

Nine of the ten patients with severe rest pain showed immediate pain relief after spinal cord stimulation. In one patient pain was reduced, but displacement of the electrode caused unpleasant painful paresthesias. After a few weeks the electrode was removed. There was no difference in subjective findings between patients with and without diabetes. During the follow-up period, amputation was necessary in three patients, including the patient in whom ESES was stopped. These patients had gangrene before ESES. In the other five of the eight patients with ischemic ulcers, complete healing occurred in two patients and an improved tissue integrity was observed in three patients.

Objective Findings

Macrocirculation. Before ESES the mean systolic ankle/arm pressure index was 32%, which did not change after treatment (Table 1). The systolic toe pressure before treatment was 9 mmHg and increased to a mean value of 19 mmHg after ESES. This difference, however, was not statistically significant.

Microcirculation. Morphologic investigation of the skin capillaries revealed that both with and without sodium fluorescein the number of perfused capillaries increased significantly ($p < 0.001$) after ESES (Table 2). In Figure 2 the capillary bed filled with sodium-fluorescein is shown before and after stimulation. The obvious avascular areas before treatment are perfused after ESES. Skin capillary diameter (15.7 μm) did not change after treatment.

TABLE 1. *Macrocirculatory Parameters Before and After ESES**

	Before	After	Significance
Systolic ankle/arm pressure index (%)	32 ± 14	37 ± 14	NS
Systolic toe pressure (mmHg)	9 ± 16	19 ± 23	NS

* Mean ± SD.
NS = not significant.

Mean RBC velocity in the control situation was 0.054 mm/sec. One day after spinal cord stimulation, RBC velocity increased enormously in all patients to a mean value of 0.762 mm/sec ($p < 0.001$). The appearance time of sodium-fluorescein in the capillary bed significantly decreased in all patients ($p < 0.001$).

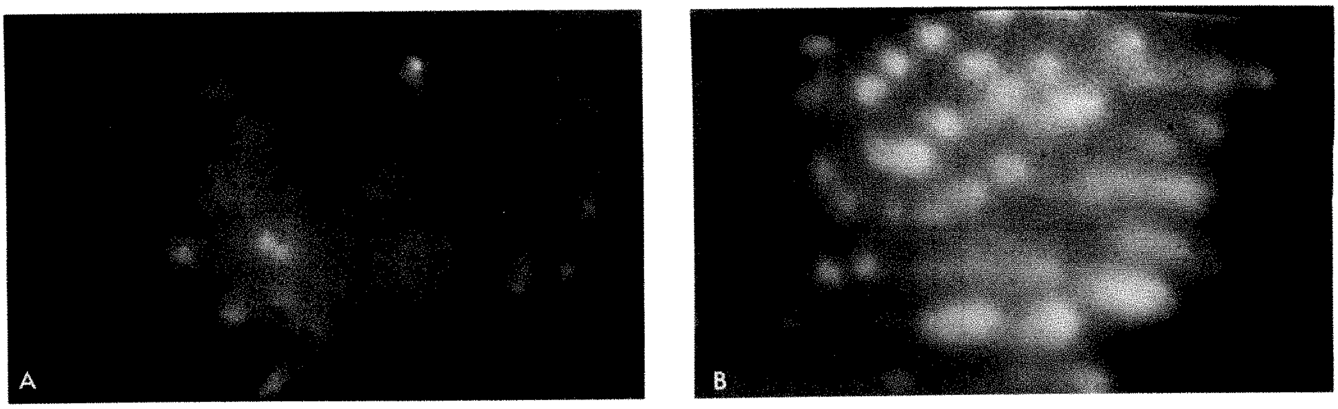
Discussion

In this study, skin capillary microscopy was shown to be a noninvasive method to evaluate microcirculatory changes induced by spinal cord stimulation. After ESES, the number of skin capillaries perfused and skin capillary RBC velocity significantly increased. The increase in velocity may be interpreted as an increase in skin blood flow rate because capillary diameter did not significantly change under these circumstances. The increase in skin capillary density and flow rate likely explain the observed clinical improvement and ulcer healing in patients with occlusive arterial disease treated

TABLE 2. *Microcirculatory Parameters Before and After ESES**

	Before ESES	After ESES	Significance
Skin capillary density (n/mm^2)	12 ± 6	30 ± 5	$p < 0.001$
Skin capillary diameter (μm)	15.7 ± 1.8	15.5 ± 1.5	NS
Red blood cell velocity (mm/sec)	0.054 ± 0.014	0.762 ± 0.205	$p < 0.001$
Sodium-fluorescein perfused capillaries (n/mm^2)	20 ± 4	44 ± 5	$p < 0.001$
Sodium-fluorescein appearance time (sec)	72 ± 15	45 ± 9	$p < 0.001$

* Mean ± SD.
NS = not significant.



FIGS. 2A and B. Skin capillary bed after injection of sodium-fluorescein before (A) and after (B) ESES.

with ESES. Theoretically, the increase in skin perfusion can be caused by improved proximal arterial inflow, an idea supported by the significant decrease in sodium-fluorescein appearance time. The enhanced flow rate, however, did not result in a significant increase in ankle and digital arterial pressure, which might be explained by still fully dilated arterioles in this situation resulting in a "sink" for flow. An alternative explanation for the increase in nutritional skin blood flow could be redistribution of flow from muscle or bone towards the skin. ESES, however, was found to enhance skeletal muscle blood flow[17] so that shunting of blood from muscle to skin is less likely.

The patients in this study were all in the last phase before amputation. Seven of the ten patients reported long-term subjective improvement after spinal cord stimulation and were free of pain, whereas in three patients amputation was necessary. These beneficial effects are in agreement with the observations of Augustinsson et al.,[18] who used ESES in patients with ischemia based on atherosclerosis, Buerger's disease, and severe vasospastic disorders. Only 38% of the stimulated atherosclerotic patients had amputation compared with 90% in a comparable group of unstimulated patients. The amputation rate was highest in patients with ulcers and gangrene before ESES, suggesting that the treatment has no limb-saving effect when there is an established partial gangrene, which is in concurrence with the results of Broseta et al.[7]

The mechanisms by which ESES exerts pain relief and improved blood flow are still unclear. Pain is a symptom of tissue damage, caused by stimulation of A-delta and C fibers, transmitted to the cells of the substantia gelatinosa, the dorsal-column fibers, and the first central transmission (T) cells in the dorsal horn. In their "gate control theory" Melzack and Wall[19] propose that pain is determined by interaction between these three transmitting systems. The theory assumes that stimulation of the larger A fibers finally results in inhibition of the T cells. Consequently, these T cells do not react anymore to pain impulses *via* the smaller fibers. The idea of dorsal root electrical stimulation is based on the activation of the larger A fibers, leading to blockade of pain stimuli. Pain relief may release the reflex vasoconstriction that is known to occur in response to pain. Whether the sympathetic nervous system is involved is unclear. Augustinsson et al.[20] observed autonomic changes after stimulation in both patients with and without pain, raising the question whether the pain-reducing effect and the autonomic effects are a consequence of or caused by a common mechanism or two parallel phenomena. According to Melzack and Wall,[19] autonomic pathways in the intermediate columns of the grey area regulate the degree of peripheral vasoconstriction. Current spread of electrical stimulation into this area theoretically releases segmental spinal reflexes, inhibiting sympathetic fiber discharge to vessels in the extremities. Owens et al.[21] demonstrated increased infrared emission after application of nerve electrical stimulation, postulating the indirect evidence of cutaneous vasodilatation and hence, decreased sympathetic tone. This enhanced skin temperature indicates that not only nutritional flow, but also arteriovenous shunt flow increases after ESES.

Another approach to vasodilatation after electrical stimulation is described by Hilton and Marshall.[17] They demonstrated vasodilatation in the cat gastrocnemius muscle after dorsal root stimulation and postulated that this effect is due to antidromic stimulation of small diameter fibers. This dilatation was unaffected by sympathetic blocking agents, but greatly reduced by prostaglandin inhibitors. They concluded that activity in the afferent fibers of skeletal muscle produces an increase in muscle blood flow, mediated by the release of prostaglandins in muscles.

In conclusion, epidural spinal cord stimulation improves skin nutritional blood flow in patients with severe lower limb ischemia, leading to wound healing and possible limb salvage. Therefore, ESES is a promising treatment in this group of patients. Especially with our forthcoming ageing population it is extremely important to perform prospective clinical and physiologic studies to clarify the indications and to investigate the mechanisms involved.

In Situ Tibial Reconstruction

State-of-the-Art or Passing Fancy

DALE BUCHBINDER, M.D., DAVID L. ROLLINS, M.D., CAROLYN M. SEMROW, B.S.E.E., JAMES J. SCHULER, M.D.,*
JOSEPH P. MEYER, M.D.,* and D. PRESTON FLANIGAN, M.D.*

To further evaluate the efficacy of *in situ* saphenous vein bypass, the authors have reviewed their experience with *in situ* bypass. Between October 1981 and December 1985, 120 *in situ* saphenous vein bypass were performed; 81 were to infrapopliteal vessels. All procedures were performed for limb salvage. The mean patient age was 74 years, and 74% were men, 57% had diabetes mellitus, 92% were smokers, and 72% had hypertension and/or coronary artery disease. All patients were evaluated by preoperative noninvasive testing and biplanar angiography. All procedures were performed by the valve incision technique. The vein utilization rate was 91%. Grafts were routinely placed into isolated tibial segments and foot vessels without evidence of a patent pedal arch. Follow-up information was obtained at 3-month intervals. Patency and limb salvage data were calculated by life-table analysis. The cumulative patency rates were 98% at 1 month, 88% at 12 months, and 82% at 50 months. These data demonstrate that the *in situ* bypass maintains an excellent patency rate and provides durable limb salvage.

IN RECENT YEARS, the *in situ* saphenous vein bypass has become increasingly popular.[1-4] Many investigators have demonstrated excellent patency rates, increased vein utilization,[1-4] as well as laboratory evidence of increased endothelial survival[5,6] and increased prostacyclin production,[6,7] which may account, in part, for observed increased patency rates. Also, many surgeons have preferred the anatomic size match-ups of the vein using the larger end to the larger common femoral artery and the smaller ends to the smaller tibial vessels instead of reversing the vein.[5,8] Most major objections to the *in situ* technique have been related to the technical nature of the procedure. Many surgeons believe that the operation is cumbersome. However, with recent advancements in instrumentation,[8] as well as the ability to map the saphenous vein before operation by B-mode ultrasound,[9,10] the procedure has become less cumbersome and more widely accepted. It is used in many centers as the primary reconstructive technique for infrainguinal arterial reconstruction.[1,5,8,11,12] The authors have reviewed their experience with 81 *in situ* bypass procedures performed to the tibial vessels to further evaluate the efficacy of the *in situ* bypass. In the past, tibial reconstructions have shown the lowest patency rates. Therefore, the authors decided that results of bypass procedures to the tibial and ankle vessels would be a reasonable method for assessing the durability of the *in situ* bypass.

Patients and Methods

Between October 1981 and December 1985, 120 *in situ* saphenous vein bypasses were performed. Eighty-one of these operations were performed to the tibial and ankle vessels. All these infrapopliteal bypasses were performed for limb salvage. Sixty-seven per cent of patients had gangrene or ischemic ulceration and 33% had rest pain. The mean patient age was 74 years, and 74% were men, 57% had diabetes mellitus, 92% were smokers, and 72% had coronary artery disease and/or hypertension. All patients were evaluated before operation with noninvasive vascular laboratory testing consisting of segmental doppler pressures and wave form analysis. All patients had preoperative biplanar angiography. Sixty-four per cent required intraoperative pre-bypass angiography to better delineate the tibial vessels. There were no attempts to locate patent pedal arches, and the only cri-

teria used for revascularization were the presence of a segment of a tibial vessel and a foot that was deemed to have a clinically salvageable walking surface. All *in situ* bypasses were performed by the valve incision technique.[8] Before operation, the saphenous vein was evaluated by palpation and inspection. Preoperative venography was not routinely performed, and in the last 22 patients, the saphenous vein was mapped using the B-mode ultrasonic imager (Fig. 1). There were 23 bypasses performed to the anterior tibial artery, 25 to the posterior tibial artery, 13 to the peroneal artery, eight to the dorsal pedis artery, and 12 to the posterior tibial artery at or below the ankle. All patients were observed after operation at 3-month intervals with segmental doppler pressure and tracings. The minimal follow-up period was 1 month and maximum follow-up period was 50 months. The average follow-up period was 12.1 months and 27 patients were observed for more than 24 months. All patency and limb salvage data were calculated by life table analysis and were compared by Z-score analysis.

Surgical Technique

The saphenous and the common femoral artery were exposed in the infrainguinal position. The common femoral deep femoral and superficial femoral artery were isolated. The saphenofemoral junction was then dissected, and the venous tributaries to the saphenous vein were ligated. The dissection of the saphenous vein was carried out onto the common femoral vein. The distal artery and the distal saphenous vein were then dissected. Early on, the saphenous vein was entirely exposed through a continuous skin incision. However, attempts were made to leave small skin bridges, especially about the knee (Fig. 2). Systemic heparin was administered, and a curved vascular clamp was placed at the saphenofemoral junction. The saphenous vein was removed with a small rim of common femoral vein. The common femoral vein was then closed with a running 5-0 or 6-0 polyprophylene suture. One to one and a half centimeters of common femoral vein was taken along with the saphenous bulb. This allowed for an easy anastomosis to the common femoral artery. There was usually a competent valve in the saphenous bulb, which was excised under direct vision. The remaining valves were then incised early on using the valve scissors and the valvulotome. In the last half of this series, the Leather intraluminal valve cutter was used to incise the valves in all veins greater than 3 mm in diameter. After the valve incision, the proximal anastomosis was usually constructed at the common femoral artery. After flow was restored in the vein, there was usually a pulsatile column of blood seen at the distal end. At this point, no attempt was made to ligate any branches of the saphenous vein. The distal anastomosis is then constructed using a continuous 6-0 or 7-0 polyprophylene suture. Arterial flow was restored to the graft. Intraoperative postbypass angiography with needle markers was used to detect branches as well as missed or partially cut valves. Also, the sterile doppler was used with distal vein occlusion to locate remaining arteriovenous fistulae. All major side branches were ligated using double hemoclips. The sterile doppler was used to determine ankle pressure. Ankle brachial indexes were also calculated in the operating room. All skin incisions were closed in the usual manner.

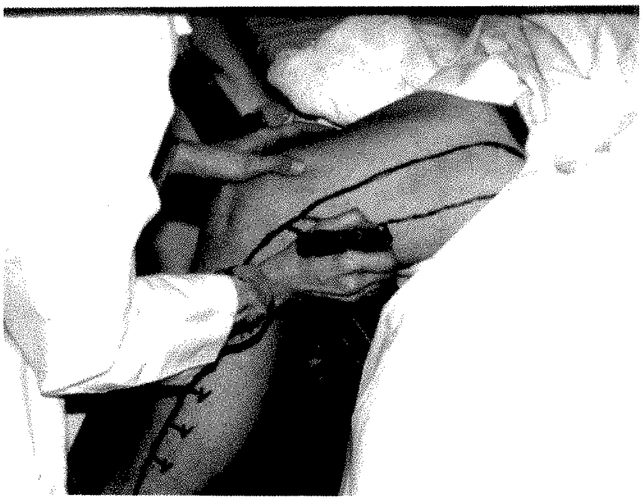

FIG. 1. B-mode ultrasound saphenous vein mapping.

Results

There were four perioperative myocardial infarctions, two resulting in death for an operative mortality rate of 2.4%. Five patients had major wound complications requiring prolonged hospitalization and there were seven

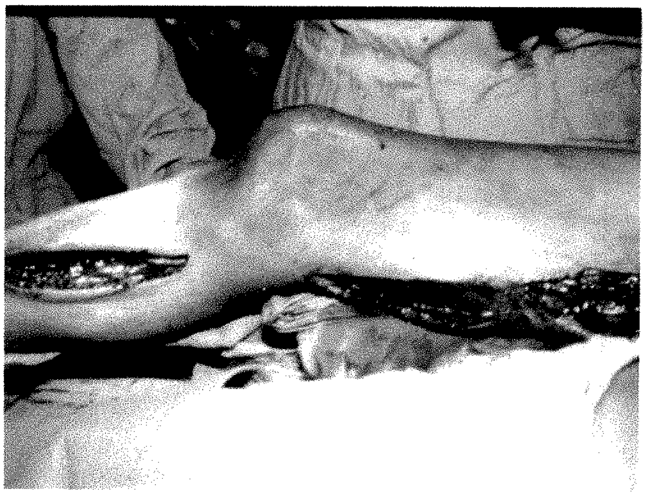

FIG. 2. Skin incision with small skin bridge.

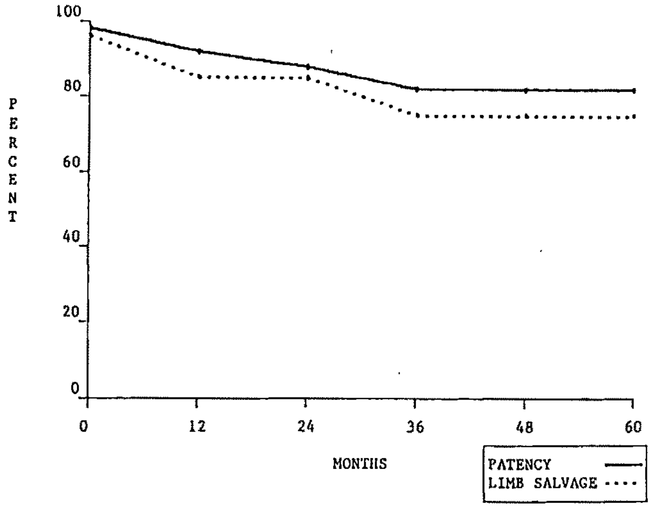

FIG. 3. Graft comparing life table analysis of graft patency and limb salvage.

minor wound complications. Five patients needed early reoperation for either missed arteriovenous fistulae or missed valve leaflets; all of these grafts were patent at the time of re-exploration. There were two patients in whom late (2 and 3 months) multiple, segmental stenosis developed in their vein bypasses. In both patients, the intraluminal valve cutter was used, and in both patients, the vein was less than 3 mm.

The cumulative patency rates were 98% at 1 month, 88% at 12 months, and 82% at 50 months (Fig. 3, Table 1). Limb salvage rates were 96% at 1 month, 85% at 12 months, and 75% at 50 months (Fig. 3, Table 2). There were 89 operations attempted and 81 completed for a vein utilization rate of 91%. The average venous diameter was 3.3 ± 0.8 mm. There were no significant differences in limb salvage and patency rates at the different anastomosis sites.

There were nine patients who required early amputation despite the presence of a well-functioning *in situ* bypass graft.

Discussion

The earliest reported *in situ* bypass was performed by Goyanes in 1906, in repairing a popliteal arterial aneurysm.[12] The idea of *in situ* bypass again emerged in the late 1950s at Saint Mary's Hospital in London, during a conversation between Carl Victor Hall, then a fellow in vascular surgery, and Charles Rob.[13] The idea of *in situ* bypass intrigued both men. Rob performed the operation by passing a blunt vein stripper retrograde down the vein, thus disrupting the valves. Carl Victor Hall returned to Oslow, and in 1962, was first to report success with the *in situ* bypass.[14] Dr. Hall performed this procedure by exposing the entire saphenous vein, and at each valve site a small transverse incision was made and the valve leaflets were directly excised.[14] The operation became popular, especially using the valve stripper in a retrograde fashion. In 1969, Barner et al. reported dismal results with the *in situ* bypass and the procedure was virtually abandoned.[15] In 1972, Leather began to reappraise *in situ* bypass, due to the continued success reported by Hall and Rostad.[16] The technique of valve incision was developed.[17] The valves were rendered incompetent by a longitudinal cut in the center of each valve leaflet, which was accomplished by passing microscissors through either the end of the vein or side branches proximal to the valves.[17] This was less trau-

matic to the vein than the retrograde valve stripper, and was easier to perform than the individual excisions described by Hall. The scissors were modified and the retrograde valvulotome was designed by modifying a Mills valvulotome. In 1979, Leather et al. reported excellent limb salvage and patency rates with *in situ* bypass using the valve incision technique.[17,18] Since that time, there have been further advances in instrumentation. The intraluminal valve cutter was also developed.

For many years, the *in situ* bypass has been compared with the "gold standard" of the reversed saphenous vein bypass. Over time, the *in situ* bypass has gained wider acceptance. This wider acceptance has been due to improved surgical techniques, the ability to use 2–3-mm veins, and demonstrably improved patency rates. These clinical data have been supported by laboratory evidence of increased endothelial survival[5,7] and increased endothelial prostacyclin production.[6,7] In a recent report by Taylor et al., the results of reverse vein bypass were compared with *in situ* bypass, thus for the first time making the *in situ* bypass the "gold standard" for infrainguinal arterial reconstruction.[19]

For the most part, the main objections to *in situ* bypass have been the technical nature of the procedure and prolonged operating times. With the advent of the intraluminal cutter and the ability to map the saphenous vein by noninvasive B-mode ultrasonic scanning, the operation has been substantially simplified. The saphenous vein has been mapped with the B-mode ultrasonic scanner in the last 22 patients in this series. The size of the vein, location of major tributaries, and valves were determined before operation. This allowed the surgeon to decrease the length of skin incisions and to locate accurately the large branches. This in turn has led to decreased operating time. Early on, the entire vein was exposed. The authors believe that this technique was valuable for learning the techniques of valve incision. However, there is some increased morbidity associated with these long skin incisions. There were five patients in this series with major wound complications requiring prolonged hospitalizations. Four of these patients had skin flap necrosis and one had a groin infection. In seven other patients, there were minor wound complications consisting mostly of minor skin edge losses. These were treated locally and did not prolong hospitalization. It is evident that in patients with minimal skin incisions there is a decreased chance of wound complications.

The average distal vein diameter was 3.3 ± 0.8 mm. This was measured with the vein distended by blood before manipulation. Fourteen veins were less than 3 mm in diameter and over 50% of the veins were judged to be inadequate for reversed vein bypass by the old minimum criterion of 4 mm. There were no attempts to define pedal arch anatomy; however, this was commonly incomplete. In 36 patients, only one tibial vessel was available for bypass. Often, this was an isolated segmental vessel (Figs. 4 and 5).

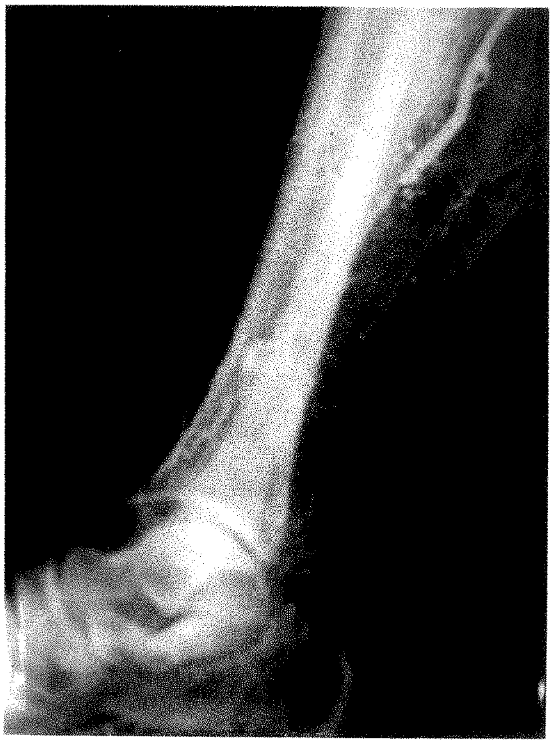

FIG. 4. Postoperative completion angiogram showing an *in situ* bypass to a distal isolated peroneal segment.

Limb salvage rates were consistently lower than patency rates. This is believed to be a function of the fact that the *in situ* graft will remain patent despite poor distal runoff. Nine patients required major amputation despite a well-functioning bypass graft. Eight of these patients were diabetics, and in this group of patients, the distal runoff was adequate to keep the graft patent but not to control the gangrene and infection.

Two patients in whom the intraluminal cutter was used later developed multiple segmental stenosis in their vein grafts. Both of these grafts failed at 2–3 months. These lesions were similar to those reported by Barner et al.,[15] and it should be noted that in both of these patients the vein diameter was 3 mm or less. Therefore, the intraluminal cutter should be used only in veins large enough to ensure that it will float freely. Recently, a 2.3-mm cutter has been developed. This cutter should be used in the smaller veins. With the advent of this additional cutter, we believe that when used appropriately, multiple segmental stenosis in the vein graft should be a decreasing problem. Despite the shortcomings in this operation of longer skin incisions and the inability to use the internal valve cutter in the smaller veins, the patency rates of 82% at 50 months and limb salvage rates of 75% at 50 months demonstrate clearly that this operation is durable. Traditionally, tibial bypass had the lowest patency rates of all infrainguinable

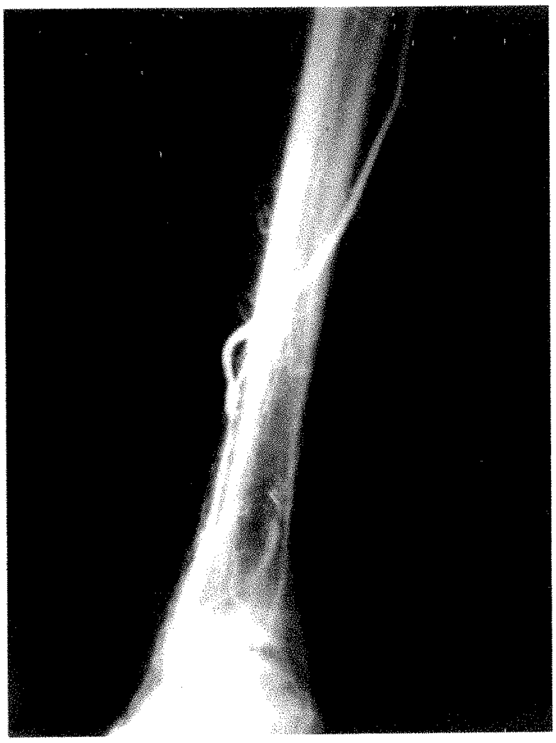

FIG. 5. Postoperative completion angiogram depicting an *in situ* bypass to a distal anterior tibial artery.

reconstructions with reversed vein and synthetic bypass grafts.[20–24] However, there does not appear to be a significant difference in patency rates between popliteal or tibial bypasses using the *in situ* technique.[1,13,25,26] It is evident from this prospective study that the *in situ* bypass offers the surgeon a reliable method for performing distal arterial reconstruction.

Therefore, in answer to the question, "is *in situ* bypass state-of-the-art or passing fancy," it is believed that this report along with others,[1–4,6,8,25,26] have shown that *in situ* bypass produces reliable results even when performed in extremely high-risk situations such as isolated tibial vessels and ankle or foot vessels. There has been increasing biochemical and structural evidence for this improved patency. With the newer techniques of valve incision, this operation is no less demanding than removing the entire saphenous vein or making composite vein grafts for harvesting arm veins or deep leg veins. Therefore, the data indicate that the *in situ* tibial bypass is a reliable method of arterial reconstruction and in many respects may be technically more rewarding than some of the reversed vein procedures. Clearly, the *in situ* bypass is no "passing fancy."

The Patient's Appraisal of the Cosmetic Result of Segmental Mastectomy in Benign and Malignant Breast Disease

LARS HOLMBERG, M.D.,* EVA ZARÉN, M.D.,* HANS-OLOV ADAMI, M.D.,* REINHOLD BERGSTRÖM, PH.D.,†
and TOM BURNS, M.D.‡

Women's appraisal of the cosmetic result and their psychosocial adjustment after a standardized segmental mastectomy for benign or malignant breast disease was analyzed on the basis of a mailed questionnaire, which was satisfactorily answered by 263 (92%) of 285 women operated on consecutively. The overall result was favorable: 96.5% of the patients found the new appearance of their breast very good (30.7%), good (44.0%), or acceptable (21.8%). Women with a benign diagnosis ran a twofold higher risk of being discontented with the new appearance of the breast than those with breast cancer. Complications of radiation therapy, preoperative concern that the breasts are important for the appearance, and anxiousness about the cosmetic result were associated with a significantly elevated risk of being less satisfied with the outcome. The main finding that it is possible to perform a locally radical operation that is highly acceptable to the woman is relevant to the surgical management of potentially malignant mammographic lesions and also to the scientific strategies for future evaluation of breast-conserving treatment modes in malignant disease.

From the Department of Surgery, University Hospital, Uppsala; Department of Statistics,† Uppsala University, Uppsala, Sweden; and Department of Psychiatry,‡ St. George's Hospital Medical School, London, England*

As a result of the evolution in breast cancer due to early diagnosis[1-4] and controlled clinical trials,[5-7] breast-conserving operations have come to play an important part in primary treatment. It is not clear, however, from the trials for evaluation of breast-conserving treatment[5-7] which is the most preferable surgical technique. Data from the NSABP trial[7] indicate that a nonstandardized local excision cannot bring the risk of local recurrences down to an acceptable level without adjuvant postoperative irradiation. If the aim of the surgical excision is local tumor control, it is therefore logical to recommend quadrantectomy or standardized segmental resection. On the other hand, it is essential to establish whether the supposed main benefits of avoiding a mastectomy—a good cosmetic result and favorable psychosocial adjustment—can be achieved when performing a larger excision than a lumpectomy.

In attempts at early diagnosis, both in daily clinical practice and in mammographic screening programs, a number of small, radiographic lesions are observed in which a definitive diagnosis cannot be made without an excisional biopsy. To avoid possible cancer cell contamination of the wound, the lesion needs to be approached with a procedure that is both diagnostic and therapeutic. On the other hand, it is important that negative cosmetic and psychological side effects do not occur as a result of excess surgical treatment in women in whom histopathologic examination has revealed a benign lesion.

Although in earlier reports of both lumpectomy plus irradiation[8-14] and segmental mastectomy with or without irradiation[7,15,16] it has been stated that a good cosmetic result can be obtained in 70–95% of the patients, data are sparse and mainly based on evaluations by physicians or hospital staff. A considerable discrepancy between the patient's and the doctor's scoring has been found in analyses in which the patient's opinion has also been recorded.[8,14-16] Clearly the patient's own viewpoint should be the most important for an uncomplicated psychosocial adjustment.

Our aim was to investigate the cosmetic result of a segmental mastectomy in a large and consecutive series of patients, as appraised by the patients themselves. We were also particularly interested in determining whether women with benign lesions undergoing segmental mastectomy had significant side effects of the treatment.

Materials and Methods

Patients

All women younger than 80 years who had consecutively undergone a segmental mastectomy for a benign or malignant lesion between October 1981 and May 1985 at Falun Central Hospital and Uppsala University Hospital were eligible for the study, which involved answering of a questionnaire 6 months or later after the operation. Six patients had died during the follow-up period and two were not approached because they were known to have disseminated cancer. This left 285 available patients. Of these, 192 were treated at Falun Central Hospital, which participated in the Kopparberg mammography screening program.[4,17] Twenty-two patients (8%) could not be analyzed because of mental illness and confusion (2 women), too many items unanswered in the questionnaire (1 woman), or nonresponse for unknown reasons (19 women). Table 1 shows some characteristics of the responders and nonresponders. Women with benign lesions and cancer *in situ* were grouped together in the analyses. Those with cancer *in situ* did not receive adjuvant treatment and were reassured by their doctors that they had a nonmalignant disease.

Women with invasive cancer measuring 2 cm or less on the mammogram and with no histopathologic signs of axillary metastases were treated routinely with segmental mastectomy. Most of them were randomly allocated, within a multicenter trial, to postoperative irradiation or to follow-up only.

The benign lesions and tumors *in situ* were considered before operation to be highly suspicious of invasive cancer, on the basis of a combination of clinical findings, fine-needle biopsy, and mammography. A definitive preoperative diagnosis was not, however, obtainable. Segmental mastectomy was performed in preference to incisional biopsy to ensure a radical procedure without contamination of the wound during operation if the lesion should be histopathologically malignant.

The individual record of each woman was reviewed regarding the histopathologic diagnosis, operative technique, and any surgical or radiologic complication.

Surgical Technique

The operative technique was highly standardized. During the first years of the study, a radial incision was used for all tumor locations. From 1983, tumors in the upper part of the breast were approached through a curvilinear incision. An overlying segment of skin was excised only if the tumor was palpable. Skin flaps were developed towards the periphery of the parenchyma and towards the central part of the breast. The radial segment was prepared by freeing it from the pectoralis muscle with the fascia included in the specimen. The segment was excised sharply, and included all breast tissue in an approximately 90-degree segment centered around the tumor. Generally, no attempt was made to approximate the incisional margins of the breast tissue. In all patients with invasive cancer, an axillary dissection was performed through a separate transverse incision in the axilla. A suction drain was used both for the breast and the axilla.

Any intra- or postoperative hematomas or seromas and any infections and/or delayed healing were regarded as surgical complications. In 58 (22.1%) women there were 80 surgical complications, the most common being seroma (23), hemorrhage (16), and postoperative infection (16).

Radiation Technique

A total of 68 patients were randomly allocated to receive postoperative irradiation with 54 Gy for 5 weeks in a linear accelerator giving 4–8 MV Rtg. The treatment was given 5 days per week with a tumor dose of 2 Gy per day, corresponding to a CRE value of 16.6. All postradiation erythema or inflammation requiring treatment or repeated consultations and all ulceration or severe breast edema were considered to be radiologic side effects. Eighteen patients had radiologic complications.

Questionnaire

A 24-item questionnaire concerning the socioeconomic background, cosmetic result, and psychosocial adjustment (Table 2) was issued to all women a minimum of 6 months after the operation. Women who did not answer were sent two reminders. The study was planned so that answers to specific questions in the questionnaire (see Table 2) were considered to be important outcomes (dependent variables), and the clinical data and answers to other questions as possible explanatory factors.

Statistical Methods

The women answered questions concerning the dependent variables on an ordinal scale with five different levels, and the dependent variables were tested one by one against the background factors in univariate analyses. Standard Chi square tests for homogeneity and the Walker-Duncan procedure described below were used in comparisons involving more than two levels for a variable. Results based on the Walker-Duncan procedure are reported, as the Chi square test does not make use of the ordinal character of the data. Fisher's exact test was used in 2 × 2 tables (which were obtained after combining categories with small numbers in certain cases).

In the multivariate analysis the fact that the dependent variable was ordinal made the standard regression model unsuitable. A generalization of the logistic model introduced by Walker and Duncan[18] was therefore used. The model assumes that the probability that the dependent variable y takes a value that is ≥j is given by:

$$P(y \geq j) = \frac{1}{1 + e^{-\alpha j - (\beta_1 x_1 \cdots \beta_p x_p)}} \quad j = 1,p$$

if there are p + 1 categories for the dependent variable with the "lowest" category (the most favorable outcome) as 0, where $x_1 \cdots x_p$ are background factors. The model was estimated by the maximum likelihood (ML) method (the SAS procedure LOGIST was used[19]). The large number of potentially explanatory variables necessitated the use of a stepwise inclusion of variables based on the efficient score statistic. A value of $p < 0.05$ was used as the criterion for inclusion of variables.

Parameter β_i shows the change in the log odds for $y \geq j$ with an increase in the background factor x_i provided that the other factors are unchanged. Thus a positive value of β_i implies an increased risk of having a less favorable cosmetic result with increasing values of the studied background factor. An odds ratio can be constructed from β_i as $OR = e^{\beta_i}$.

Results

Univariate Analysis

Impact of clinical data. Table 3 gives the distribution of answers to five of the main outcomes. The ratings indicating an unfavorable outcome were few. A higher frequency of women with a benign diagnosis than of those with invasive cancer found the treated breast unattractive (Table 3; p = 0.01). The distribution of ratings in the two diagnostic groups were not significantly different concerning other parameters. Age, tested as a continuous variable, did not have any significant impact on the women's appraisal of the outcome. Of the women with a medial tumor location, 13.7% reported declining sexual activity compared with 4.1% of those with a tumor in the lateral or central part of the breast. The surgeon's choice of a radial or curvilinear incision did not affect the cosmetic result as evaluated by univariate analysis.

TABLE 2. *Information Included in the Analysis*

  Tumor diameter
  Surgeon
  Incision
  Intra- or postoperative complications
  Postoperative radiotherapy
  Radiologic complications
  Interval operation/inquiry
  Age

Questionnaire data: background factors
  Place of residence
  Civil status
  Number of children
  Occupation
  Education
  Whether the woman considered before operation that the breasts are important for the appearance.
  Whether there was any worry before operation about the cosmetic result.

Dependent variables
  The current appearance of the breast.
  Participation in swimming, sports, and physical training after the operation.
  Feelings about seeing oneself naked after the operation.
  Tactile sensations from the breast after the operation.
  Feelings about showing oneself naked to the family or close friends after the operation.
  Psychological distress due to the new appearance of the breast.
  Changes in sexual relations after the operation.

Impact of background factors. Among the women who were gainfully employed, 5.7% were dissatisfied with the postoperative appearance of the breast compared with 0.8% of the retired women. Neither marital status, type of employment, nor education was significantly related to any of the outcome variables (Table 2) in the univariate analysis.

Of the women who had considered their breasts as important or very important to their appearance before operation, only 33.6–37.5% reported that they did not experience unease in seeing themselves naked after the operation compared with 57.1% of those who had rated their breasts unimportant in this respect. The latter also reported less psychological distress (85.7% reported no distress at all *vs.* 62.5%). Unpleasant tactile sensations in the breast and a decreased inclination on the part of the woman to show herself naked to the family or close friends after operation were also associated with anxiousness about the cosmetic result before operation.

Multivariate Analysis

Impact of clinical data. The results of the multivariate analysis are presented in Table 4. The relationship between the few ratings indicating an unfavorable result and the background factors are shown only when odds ratio (OR) significantly (95% confidence interval) differed from 1.0. The diagnosis of benign *versus* malignant still only influenced the woman's opinion of the new appearance of her breast. Radiologic complications resulted in an approximately fivefold increased risk of

* Results are given for malignant and benign or *in situ* lesions separately; the only significant difference between the groups concerned the new appearance of the breast. The sum total figure denotes how many of the 263 questionnaires could be analyzed regarding the particular question.

reluctance to participate in swimming and to show oneself naked to the family or close friends. Women operated on with a curvilinear incision ran a higher risk (OR = 1.8) of being discontented with the new contour of the breast than those with a radial incision. Operations for tumors in the medial quadrants of the breast entailed a twofold increase in the risk of psychological distress and, parallelling the results of the univariate analysis, a fourfold higher risk of deteriorated sexual relations.

Impact of background factors. As with the univariate analysis, women working outside the home ran a 2.3 times higher risk of being discontented with the appearance of their breast after the operation than the retired women. They were also more negative about seeing themselves naked, as also were women with upper secondary school or higher education (Table 4).

Women who reported preoperative anxiety about the cosmetic result ran an approximately three times higher risk of having unpleasant tactile sensations from the treated breast, unease in showing themselves naked, or suffering psychological distress than those who did not report such anxiety. Those who had rated their breasts as important for their appearance disliked seeing themselves naked and showed high indications of psychological distress about twice as often as those who had not (Table 4).

TABLE 4. *Results of the Walker-Duncan Analysis**

Result Variable	Background Factor	OR	C.I. 95%
What do you think of the appearance of the treated breast?	Gainfully employed	2.3	(1.4–3.7)
	Benign or cancer *in situ* (vs. malignant)	2.1	(1.3–3.4)
	Curvilinear incision (vs. radial)	1.8	(1.1–3.2)
Do you still participate in activities such as swimming, sports, physical training?	Radiologic complication	5.5	(1.3–23.9)
How do you feel about seeing yourself naked since the operation?	Gainfully employed	2.3	(1.4–3.9)
	Education (upper secondary school or more, vs. lower)	3.0	(1.3–6.7)
	Breast important to appearance	2.0	(1.2–3.3)
	Radiologic complication	2.8	(1.1–7.3)
How does it feel to touch the treated breast?	Preoperative anxiousness about the cosmetic result	3.3	(1.6–6.9)
How do you feel about showing yourself naked to the family or close friends since the operation?	Radiologic complication	4.8	(1.5–15.2)
	Preoperative anxiousness about the cosmetic result	3.4	(1.3–8.8)
Has the changed appearance of the breast been a psychological strain on you?	Preoperative anxiousness about the cosmetic result	3.3	(1.5–7.1)
	Tumor in medial part	2.2	(1.2–4.0)
	Breasts important to appearance	2.0	(1.1–3.9)
Have your sexual relations changed since the operation?	Tumor in medial part	4.0	(1.5–10.6)

* The statistically significant results are given as the odds ratio (OR) with 95% confidence limits (C.I. 95%) for reporting stepwise a less satisfactory result for the seven main outcome variables. Compare Table 2 for alternative answers given for five of the questions.

Discussion

The women in this study were recruited from a comprehensive and unselected population. Facilities for private care of breast cancer patients were not available in the two counties. The same diagnostic and therapeutic strategy, including the surgical technique, was used and the two surgical clinics participated in the same clinical trial for breast-conserving therapy. Few eligible women were excluded because of death or disseminated disease and a high response rate (92%) was achieved. Nonresponders were slightly younger and predominantly operated on for benign disease and probably were not as concerned about the disease and the cosmetic outcome.

Once local tumor control has been achieved, the main goal of breast-conserving therapy as compared to mastectomy is a good cosmetic result in conjunction with a favorable psychosocial adjustment. The study design allowed us to assess the outcome from this perspective. The overall cosmetic result was good and the social life and sexual relations of the patients were largely unaffected. If the cosmetic result is one determinant of psychiatric problems reported after breast cancer therapy, our results indicate that its impact is weak after a segmental mastectomy. Indeed, the overall number of side effects was so low that prudence is advisable in interpreting the results concerning single explanatory variables. Some of the statistically significant differences could have occurred by chance.

We were unable to define particular preoperative characteristics entailing a high risk of developing a strong negative reaction after operation. Two psychological factors, however, seemed to be associated with a poor outcome, namely preoperative concern about the cosmetic result and a high evaluation of the breasts for personal appearance. This finding is in accordance with risk factors found for psychological distress after mastectomy.[20] It is possible that these are important prognostic factors, but the observation must be interpreted cautiously, since it could be due to artefacts of recall bias. Women with a poorer cosmetic outcome may remember their preoperative uneasiness better.

One major finding was that although women with a benign diagnosis gave poorer ratings for the appearance of the breast, they did not report more psychological distress or other negative outcomes. The type of incision used did not have the importance for the patients' appraisal of the result suggested in other studies.[8,11,12] However, the operations analyzed here were performed with a standardized technique in patients who were all presumptive candidates for a prospective randomized trial. This probably tends to unify and raise the standards of treatment. Complications of radiotherapy impaired the cosmetic result even when surgical complications were taken into account in the multivariate analysis.

In studies on psychological consequences of mastectomy, divorced women and women in an unhappy marriage reacted more often with depression.[21,22] In the current study, however, being single or divorced did not increase the risk of an unfavorable assessment of the cosmetic result.

The significance of the only major argument against a segmental mastectomy as compared to lumpectomy, which is an inferior cosmetic result, is contradicted by the results of this study. It is of great strategic importance for the treatment of small lesions of the breast that a locally radical operative procedure can be done without serious psychological side effects. The routine acceptance of such an operative procedure would confer two major benefits. First, in those cancer patients where breast-conserving therapy is appropriate, it would avoid time spent in evaluating minimal or nonstandardized surgical techniques. These appear to give inferior local control of disease as indicated by the high rate of recurrences located primarily to the site of earlier surgery.[7,23,24] It would be more important, having accepted such a procedure as standard, to critically assess the role of postoperative radiotherapy in local tumor control. Second, in a screening situation it would be preferable, provided that the specificity of the screening is the same as that in the current setting,[4] to decide on a radical excision of lesions suspected, but as yet not proven, to be cancerous. This would avoid contaminating the wound if the lesions were histopathologically malignant.

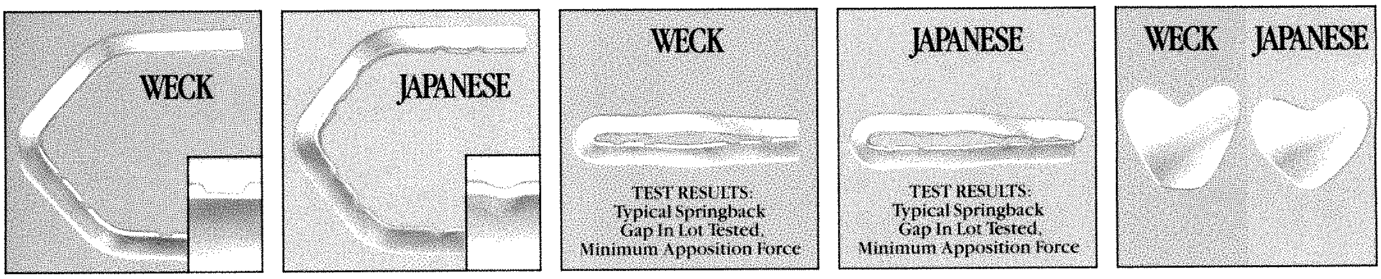
Hemoclip® ligating clips are made for blood vessels.

That sounds obvious, but it's not to everyone.

It's not easy to make ligating clips that are finely balanced between strength and malleability–two desirable ligating clip properties.

But in a quarter-century of manufacture, Weck has learned to do the job on this key implant device as no one else has.



The Hemoclip® ligating clip is coined with distinct rectangular transverse grooves, designed for longitudinal gripping power. Clip wire is processed metallurgially for malleability in closure. The Japanese imitation clips have shallow-drawn wire, and smaller, rounded transverse grooves. Deeper Hemoclip® wire shape aids retention in Weck appliers. (Typical closure illustrated from independent study.)

But now there's a problem you should be aware of. Some U.S.-based companies have begun distributing–not manufacturing–Japanese imitations of the Hemoclip® ligating clip. These clips are not the product of Weck manufacturing expertise and the technical performance of these clips is simply not the same as that of Hemoclip® ligating clips, an exclusive Weck product.

They may look the same, but they're not.

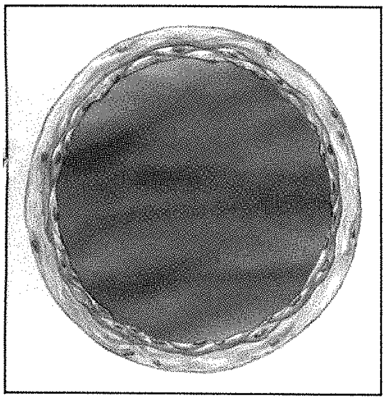
The recently-introduced Japanese clips look the same as Hemoclip® ligating clips to the naked eye. But a recently completed independent lab study of sample quantities of clips confirms Weck's own observation of substantial differences in closure properties between the Japanese clips and Weck clips.

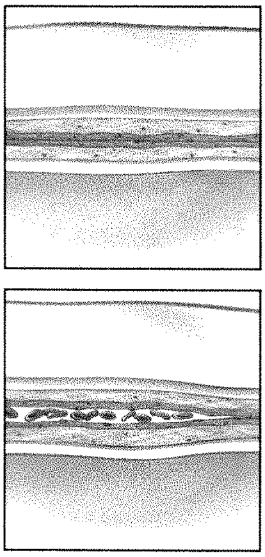
Vessel walls may be as thin as one-twelfth of vessel diameter.

Veins, in contrast to arteries, have very thin walls. When you consider that the vein tributaries ligated in surgery are sometimes one millimeter in diameter or smaller, with combined vessel walls as small as seven-thousandths of an inch (178 microns), according to animal studies on comparable vessels, you can appreciate the functional importance of differences in closure gap.

Arterial tributaries can be tiny, too, and although their walls are generally thicker than vein walls, arterial pressure is higher than venous pressure.

It seems prudent to employ ligating clips which offer the response and clip-closure performance Weck usage has established in your surgery.





ABOVE. A vein tributary of 1mm can have a combined wall thickness of just seven-thousandths of an inch (178 microns), according to animal studies. RIGHT. A ligating clip that demonstrates greater springback than the clip you have regularly used for such vessels may be more likely to leave a closure gap larger than the vessel-wall thickness of a tiny vessel.

Weck's titanium clip vs. their titanium clip. A 23-27% difference.

Examine the chart for a visual representation of the difference in closure springback an independent research firm discovered between a set of Weck titanium medium-size clips and a set of Japanese titanium medium-size clips obtained directly from U.S. distributors of those clips. Both sets of clips were closed in Weck appliers through use of force-control devices.

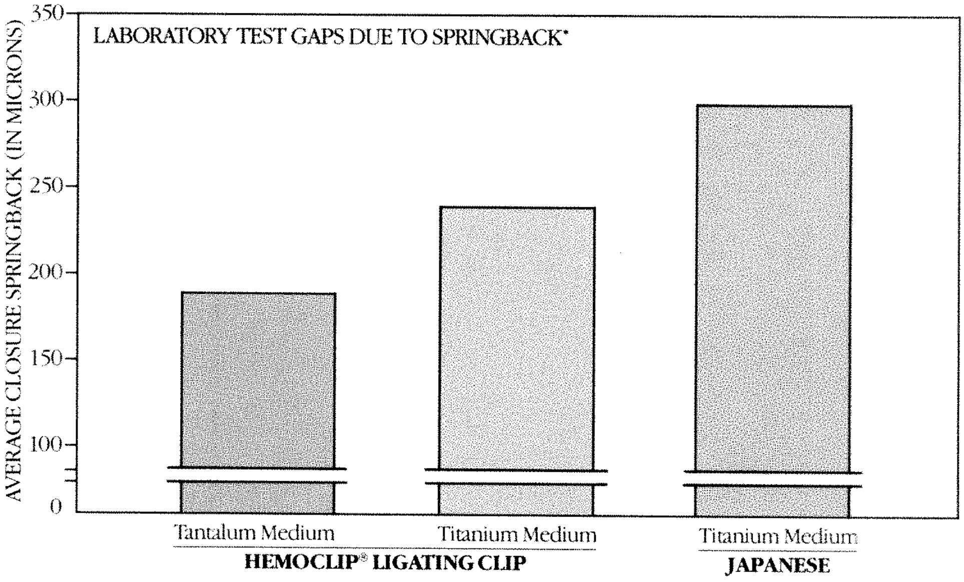
Closure of two sample sets of 25 Japanese titanium medium clips at forces adequate to achieve initial complete touching along clip legs resulted in closures of about 12 thousandths of an inch (305 microns) for the Japanese clips, 23-27% larger than the Weck titanium clip closure gap.

Weck's tantalum clips vs. their titanium clips. A 56% springback difference.

The comparison of Japanese titanium with Weck tantalum clips is even more important.

The Japanese companies make only titanium clips, and so they have sold hard on the benefits of titanium.

Tantalum is a softer material known for excellent clip closure. And the study revealed 56% and 61% larger mean closure gaps after springback for two sets of Japanese titanium clips, a ringing endorsement of the closure advantages of the Weck tantalum clips tested.



An independent lab study on two sample sets of 25 Japanese imitation clips vs. Weck clips found that the Japanese medium-size clips, closed to initial complete touching of clip legs, evidenced mean closure gaps, due to springback, 23-27% larger than Weck medium-size titanium clips, and 56-61% larger than Hemoclip® tantalum clips from Weck. Other sizes produced similar results. (Closure gap in microns-one micron = one thousandth of one millimeter).

---

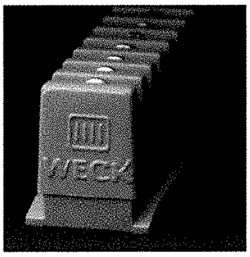
*Stronger closure forces would likely be employed during actual surgery cases.

The comparison was similar for Weck stainless vs. Japanese titanium, with the stainless scoring substantially smaller gaps after springback.

Odds are, if you are using Weck clips you are accustomed to tantalum or stainless steel clip closure, because the vast majority of Weck accounts use these two metals.

And a new Weck-funded NMR major-university study indicates that magnetic deflection of tantalum clips is negligible, just as it is for titanium clips. So if your local competitive salesman distributing Japanese clips tries to convince you that titanium clips are exclusively acceptable for NMR magnetic deflection in preference to tantalum, we suggest you cite the new Weck-sponsored university study.

Look for the Weck name on the cartridge.



To visually and quickly confirm that you really are using Weck clips, look at the end of the clip cartridge. If you are using Weck clips, you should see there the Weck name molded into the plastic. The Weck name is your assurance of genuine Hemoclip® clip processing experience and knowledge.

The Effect of Hemorrhage and Resuscitation on Serum Levels of Immunoreactive Atrial Natriuretic Factor

STEVEN R. SHACKFORD, M.D., F.A.C.S., CHARLES H. NORTON, M.D., MICHAEL G. ZIEGLER, M.D., and KEITH D. WILNER, PH.D.

From the University of California San Diego Medical Center, San Diego, California

To determine if atrial natriuretic factor (ANF) might have a role in blood volume regulation during hypovolemia, the serum level was measured before and after hemorrhage and resuscitation (RESUS) in a porcine shock model. Hemorrhage of 40% of the blood volume produced significant ($p < 0.01$) decreases in mean arterial pressure, central venous pressure, and cardiac output and a significant increase in heart rate (HR), plasma renin activity, and catecholamines ($p < 0.01$). Hemorrhage was also associated with a significant increase in ANF ($p < 0.05$). All parameters except HR returned to baseline values with RESUS. The rise in ANF associated with moderate hemorrhage was unexpected, but may have been due to the profound tachycardia or decreased degradation during shock. Sodium excretion and urine flow increased significantly with RESUS without an associated increase in ANF, suggesting that ANF may not be involved in the early phase of postresuscitation diuresis.

ATRIAL NATRIURETIC FACTOR (ANF), a peptide produced by mammalian atrial cardiocytes, may play a major role in fluid and electrolyte homeostasis, control of vascular tone, and regulation of blood volume.[1] It is known to have potent natriuretic, diuretic, and vasorelaxant properties in euvolemic and hypervolemic states.[2,3] Stimuli for the release of ANF include tachycardia,[4,5] atrial distention,[6] and hyperosmolarity.[7] Elevated serum levels of ANF, determined by radioimmunoassay (immunoreactive ANF [irANF]), have also been found in patients with congestive heart failure.[8] There has been no investigation of irANF during hemorrhagic hypovolemia, a physiologic state characterized by major shifts in fluids, significant alteration in vascular tone, and sodium and water retention. There also has not been any exploration of a possible role for ANF in the marked diuresis and natriuresis that occurs after resuscitation from hypovolemic shock. To determine if ANF might be involved in blood volume regulation during and after shock and resuscitation, we measured serum levels of irANF before and after hemorrhage and resuscitation in a porcine model of severe hypovolemic shock.

Materials and Methods

Twelve mature swine (5 males, 7 females) weighing 28–34 kg underwent general endotracheal anesthesia with halothane 0.5–1% for placement of catheters for blood sampling and hemorrhage and for measuring mean arterial pressure (MAP), central venous pressure (CVP), pulmonary artery wedge pressure (PWP), and cardiac output (CO) by thermodilution.[9] A catheter was surgically placed in the bladder for obtaining urine samples and measuring output. After recovery from anesthesia, the animals were returned to their cages. After an overnight fast, the unanesthetized, fully awake pigs were returned to the study area and allowed to acclimate to their surroundings. Baseline (BL) measurements of heart rate (HR), MAP, CVP, PWP, CO, and urine output (UO) were recorded. Serum and urine samples were obtained for measurement of sodium and creatinine concentration and osmolarity. Sodium concentration in the urine and serum was determined by flame photometry, creatinine by the ASTRA Ideal System picric acid rate reaction (Beckman Instruments, Fullerton, CA), and osmolarity by vapor pressure changes.[10] Cardiac stroke volume (SV) was calculated by dividing the CO by the HR. Urine flow rate was calculated by dividing

TABLE 1. *The Effect of Hemorrhage and Resuscitation on Hemodynamic Parameters* (Mean ± SEM)*

Parameter	Baseline	Immediately after Hemorrhage	Immediately after Resuscitation	24 Hours after Hemorrhage (D_1)
MAP (mmHg)	106 ± 2	53 ± 6*	101 ± 5	102 ± 4
HR (beats/min)	113 ± 11	187 ± 13*	145 ± 10†	120 ± 8
CO (L/min)	3.3 ± 0.2	1.6 ± 0.2*	3.6 ± 0.1	3.9 ± 0.2*
SV (ml/beat)	31 ± 3	8 ± 1*	26 ± 2	34 ± 2
PWP (mmHg)	9.3 ± 0.8	7.2 ± 1.2	10.5 ± 0.8	8.9 ± 0.7
CVP (mmHg)	4.0 ± 0.9	0.4 ± 1.2*	3.8 ± 0.9	3.4 ± 0.8

All values compared with baseline: * $p < 0.01$; †$p < 0.05$.

the UO by the duration in minutes of the interval of collection. Additional serum was collected in chilled plastic tubes, immediately placed on ice, centrifuged at −4 C, and the supernatant stored at −70 C for the later determination of irANF and plasma renin activity (REN) by radioimmunoassay (RIA),[11,12] and epinephrine (E) and norepinephrine (NE) by radioenzymaticassay (REA).[13] After the BL measurements and sampling were complete, the pigs were bled 40% of their calculated blood volume[14] over 30 minutes. The shed blood was centrifuged for later administration as packed red blood cells (PRBC). After an additional 30 minutes, resuscitation (RESUS) was begun with crystalloid solution, either Ringer's lactate (RL:sodium = 130 mEq/L; osmolarity = 274 mOsm/L) or hypertonic sodium lactate (HSL:sodium = 250 mEq/L; osmolarity = 512 mOsm/L). After an additional 60 minutes (120 minutes after the initiation of hemorrhage), shed PRBC were administered to return the hematocrit to approximately two thirds of the BL value, and additional crystalloid, RL or HSL, was administered to maintain the CVP at BL value. Measurements were repeated hourly for 24 hours. Serum hormone determinations and serum and urine sodium, creatinine, and osmolarity determinations were repeated at the completion of hemorrhage, immediately after RESUS and 24 hours after hemorrhage. Resuscitation was believed to be complete when the MAP and CVP were stable at BL values. The animals were given nothing orally during the 24-hour study. At the completion of the study they were returned to their cages and given food and water *ad libitum.*

The irANF was measured using a modification of the radioimmunoassay of Gutkowska et al.[11] and Napier et al.[15] The assay sensitivity was 40 pg/ml and the within-assay coefficient of variance was 5%. Specimens from a single animal were run with the same assay.

The assay is specific for ANF and closely related peptides. The antibody used does not cross-react with somatostatin, oxytocin, or vasopressin. The antibody does cross-react with longer peptides that contain the ANF molecule such as atriopeptin I (3%) and atriopeptin II (27%). It also cross-reacts with fragments of ANF so that the peptide containing amino acids 18–28 shows a 57% cross-reactivity. However, none of these related peptides were found to be present in significant quantities in the blood of any animal.

Comparisons were made using the Student's t-test for paired and unpaired data, one-way analysis of variance, and the Wilcoxen two sample rank sum test. All computations were performed using the BMDP statistical analysis software and the Clinfo Database Management System (University of California Press, Berkeley, CA). Significance was attributed to a value of $p < 0.05$. All values are expressed as mean ± SEM.

Results

The swine were bled an average of 883 ± 24 ml, or 28.3 ± 0.1 ml/kg. This degree of hemorrhage produced significant decreases in CO, SV, MAP, and CVP, and a significant increase in HR (Table 1). Resuscitation required a volume of 2507 ± 294 of RL or 1575 ± 132 of HSL ($p = 0.01$) and 157 ± 13 ml of packed red blood cells. This returned all of the hemodynamic parameters to a value equal to or greater than the BL value. The HR was significantly elevated after resuscitation, but was not significantly different than BL at D_1 (Table 1).

Hemorrhage produced significant elevations in all of the hormones. The increase was greatest for the catecholamines and REN, reflecting the severity of the model (Table 2). The 10-fold increase in REN indicated that the hemorrhage had severely contracted the extracellular fluid volume. There was a significant increase in irANF associated with hemorrhage (Fig. 1). The 34% increase in irANF was less pronounced than the elevations in the other hormones. After fluid resuscitation, REN and irANF had returned to BL, whereas E and NE were still elevated. All hormone concentrations returned to BL by 24 hours after hemorrhage, except irANF, which was significantly lower at D_1 than at BL.

The evaluation of renal function during hemorrhage was made on urine samples collected over 1 hour beginning with the initiation of hemorrhage and ending just before the start of resuscitation. Generally, urine output in all animals was unchanged from BL during the first

TABLE 2. *The Effect of Hemorrhage and Resuscitation on Plasma Catecholamines and Renin Activity (Mean ± SEM)*

Hormone	Baseline	Immediately after Hemorrhage	Immediately after Resuscitation	24 Hours after Hemorrhage (D_1)
Epinephrine (pg/ml)	182 ± 47	9600 ± 2488*	335 ± 70†	253 ± 76
Norepinephrine (pg/ml)	427 ± 48	8140 ± 2557*	788 ± 180†	442 ± 38
Renin (mg/ml/h)	1.6 ± 0.3	17.1 ± 2.2*	1.4 ± 0.2	1.3 ± 0.2

All values compared with baseline: * $p < 0.01$; †$p < 0.05$.

20 minutes of hemorrhage, but decreased sharply thereafter. Urine output approached zero in all animals during the last 10–15 minutes of the collection period. Hemorrhage and resuscitation produced major changes in renal function (Fig. 2). Hemorrhage caused a decrease in creatinine clearance, which was reversed with resuscitation. Urine flow decreased with hemorrhage, but increased significantly with resuscitation and remained elevated on D_1. Sodium excretion during the 1-hour interval of collection was unchanged from BL, but decreased with the fall in urine flow during the 30-minute interval before initiating RESUS. Sodium excretion increased significantly with resuscitation and continued to increase on D_1.

Crystalloid was administered throughout the first 24 hours to maintain the CVP at BL value resulting in a net accumulation of sodium (305 ± 32 mEq) and water (1560 ± 296 ml) by D_1 (Fig. 2). The amount of sodium required to resuscitate the animals and to maintain hemodynamic stability was approximately 2.2 times the amount of sodium lost.

The finding of a significantly increased irANF with hemorrhage was unexpected. We postulated that the tachycardia that occurred with hemorrhage may have caused the increased release of irANF as described by others.[4,5] To investigate this possibility, we attached

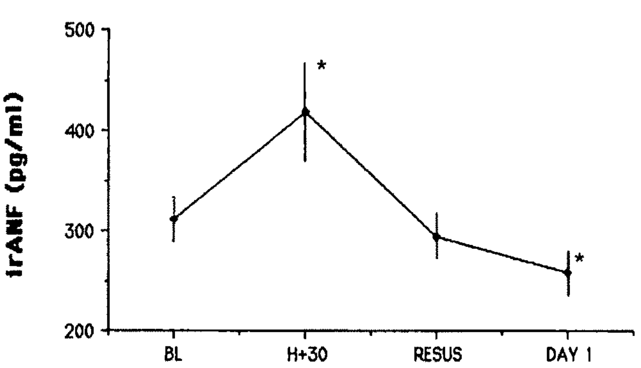

FIG. 1. The effect of hemorrhage and resuscitation on serum levels of irANF. Hemorrhage was associated with a significant increase in irANF. BL = baseline; H + 30 = immediately after hemorrhage; RESUS = immediately after resuscitation; DAY 1 = 24 hours after hemorrhage. Bars indicate SEM. All values compared to BL, *$p < 0.05$.

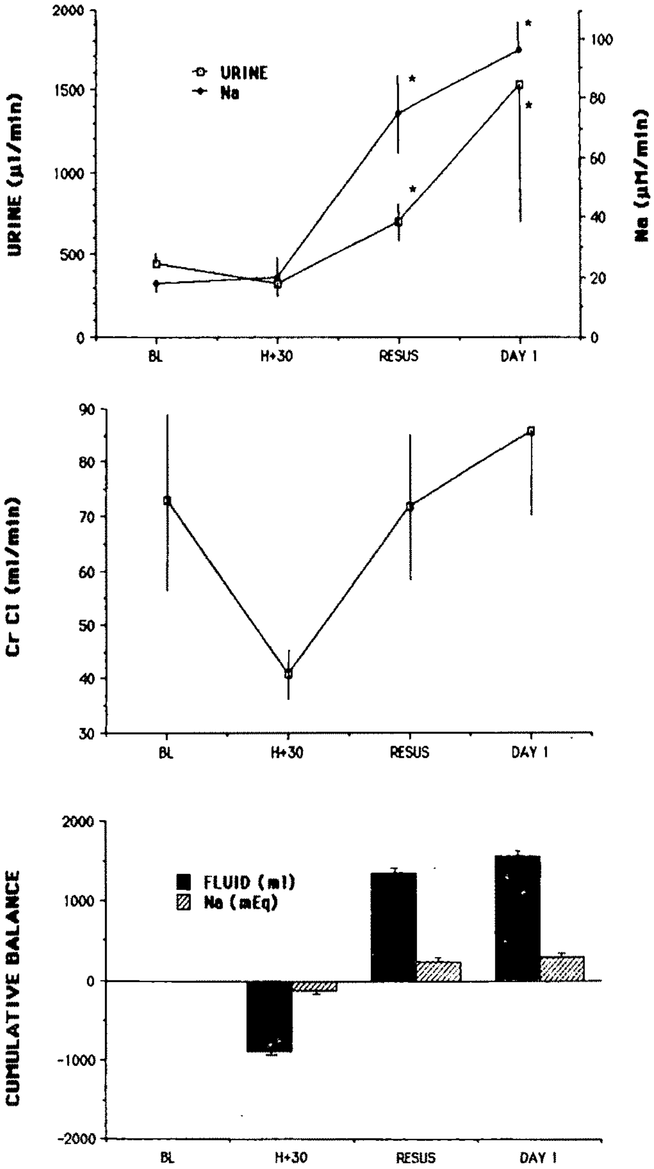

FIG. 2. The effect of hemorrhage and resuscitation on renal function. Top panel shows urine flow (URINE) and sodium excretion (Na). Middle panel shows creatinine clearance (Cr Cl). Bottom panel shows the cumulative fluid and sodium balances. Urine flow and Cr Cl fell with hemorrhage. Cr Cl normalized with resuscitation while urine flow and sodium excretion increased significantly. BL = baseline; H + 30 = immediately after hemorrhage; RESUS = immediately after resuscitation; DAY 1 = 24 hours after hemorrhage. Bars indicate SEM. All values compared to BL; *$p < 0.05$.

TABLE 3. *The Effect of Atrial Pacing on irANF Levels (Mean ± SEM)*

	Baseline	During Pacing
HR (beats/min)	111 ± 15	170 ± 8*
CO (L/min)	2.6 ± 0.7	2.1 ± 0.6
CVP (mmHg)	7.8 ± 1.8	7.0 ± 2.4
ANF (pg/ml)	281 ± 67	528 ± 96*

All values compared with baseline: * $p < 0.05$.

All values compared with baseline: * $p < 0.05$.

pacing wires to the right atrium with surgical clips through a median sternotomy under a general anesthetic (halothane 0.5–1.0%) and measured CO, CVP, HR, and irANF after the sternotomy and placement of the pacing wires and during atrial pacing in five additional pigs. Pacing produced significant increases in HR and irANF, whereas CO and CVP decreased slightly (Table 3). The amount of increase in irANF with pacing was variable in each individual pig (Fig. 3).

To determine if the swine exposed to severe shock and allowed to recover could release irANF in response to volume loading, we restudied five animals 96 hours after the completion of shock experiments. Fluid (1–2 L of crystalloid) was rapidly infused into the central circulation to produce at least a threefold rise in CVP. Cardiovascular parameters and irANF were measured before and at the end of the fluid infusion. Rapid fluid infusion significantly increased the CO, CVP, and irANF (Table 4). Although the HR increased with fluid infusion, the rise was not significant. The individual increases were more pronounced with fluid infusion than those observed with atrial pacing (Fig. 4). A pronounced diuresis followed the fluid infusion and the irANF elevation. For the 10-minute interval immediately after the infusion, the urine flow rate increased to 3.1 ± 1.7 ml/min and for the initial 30 minutes the average urine output was 2.5 ± 0.5 ml/min.

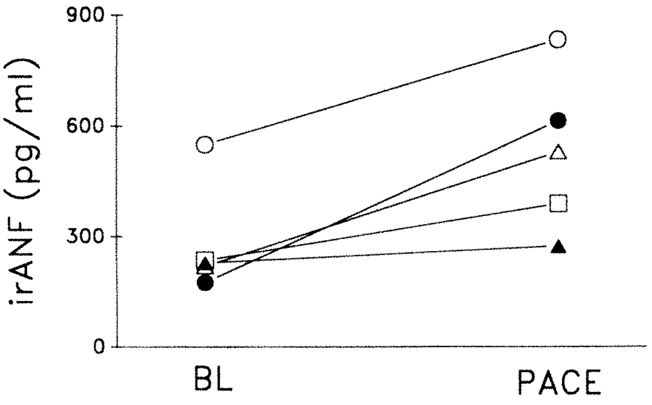

FIG. 3. The effect of atrial pacing on serum levels of irANF in five swine. The irANF increased with pacing, but the amount of increase was variable. BL = baseline; PACE = during pacing.

Finally, we compared the irANF levels in animals resuscitated with RL with those resuscitated with HSL to determine if serum osmolarity or sodium concentration affected the levels of irANF after hemorrhage and resuscitation (Table 5). There were significant differences between the RL and HSL groups in serum sodium and osmolarity at RESUS and at D_1. However, there was no difference between the groups in the irANF level measured at these intervals.

Discussion

A relationship between the heart and the kidney in the control of blood volume has been suspected for 40 years.[16] This relationship was confirmed when de Bold and co-workers demonstrated that extracts of rat atria produced a profound natriuresis and diuresis.[17] Subsequent work has shown that the atrial extracts have vasorelaxant properties as well.[18,19] The active material appears to be located in the paranuclear region of the cardiocyte[20] and to consist of small related peptides that have now been identified, sequenced, and synthesized.[21] Release of these peptides has been linked primarily to atrial distention,[6] usually associated with increased cardiac filling pressures.[8] Other possible stimuli for release include hyperosmolarity[7] and tachycardia.[4,5] Since tachycardia and wall tension induced by atrial stretching are believed to release ANF, it seemed that the release mechanism could be further elucidated by measuring irANF in a physiologic state characterized by tachycardia and hypovolemia.

We selected a model of severe hemorrhage (40% of the blood volume) over a short period (30 minutes). This model has an expected mortality rate of approximately 20%.[22] We delayed the initiation of resuscitation for 30 minutes to conform to the usual clinical scenario. The severity of this model was reflected in the cardiovascular and humoral responses. There were significant decreases in CO, SV, MAP, and CVP and significant increases in E, NE, and REN.

It was unexpected that hemorrhage would result in a significant increase in irANF. Although this increase was relatively small compared with the catecholamines and renin, the increase was notable in view of the profound hypovolemia. One explanation for this increase is that it was due to the rise in heart rate. Others[4,5] have observed an increase in irANF associated with atrial tachycardia. However, in those experiments and observations, atrial wall tension may have contributed to the rise in irANF since there was an associated increase in either right atrial pressure or CVP. In the experiments described here, there was a significant decrease in CVP associated with tachycardia; therefore, a rise in atrial wall tension is unlikely to have contributed to the observed increase in irANF. When atrial pacing was induced in euvolemic swine, the associated increase in irANF was greater than that observed with tachycardia and a decreased CVP in the hypovolemic swine. Rapid fluid infusion in the euvolemic swine was associated with a sharp increase in CVP and was associated with the greatest increase in irANF. Tachycardia associated with increases in wall tension may act synergistically to increase irANF. The release of irANF in these swine had the anticipated effect of increasing urine flow (and, presumably, sodium excretion). However, as Goetz et al.[23] have pointed out, the increase in urine flow may be entirely or partly due to the effects of wall tension mediated by vagal afferents.

The release of irANF in severe hemorrhage could have been related to the presence of other hormones associated with the shock state. Clearly, catecholamines could have been responsible since the irANF increase coincided with increases in E and NE. However, irANF had returned to BL value at RESUS when E and NE were still significantly elevated. Possibly, irANF could have been released in association with the release of vasopressin. Vasopressin is known to be released after hemorrhage[24] and has been observed to increase irANF in euvolemic rats.[25] In addition, some have suggested the possibility that irANF and vasopressin are functional antagonists and exist in a negative feedback relationship.[25]

The observed increase could also be explained by a decrease in the degradation of the peptide associated with an unchanged basal secretion rate that was unaffected by the contraction of the plasma volume. This is a plausible explanation of our observations since the magnitude of decrease in the vascular volume (40%) was similar to the magnitude of increase in irANF (34%). A basal secretion rate unaffected by severe hemorrhage suggests that ANF may have a physiologic role in the response to hemorrhage, perhaps as an antagonist to the endogenous vasoconstrictors released during shock. Indeed, ANF has been shown to antagonize NE-induced vasoconstriction[26] and to reverse NE-induced acute renal failure.[27]

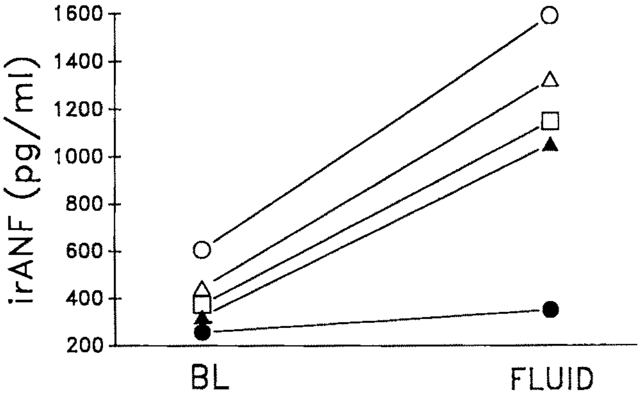

FIG. 4. The effect of rapid fluid infusion on serum levels of irANF in five swine. The irANF increased with fluid infusion. BL = baseline; FLUID = immediately after infusion.

We observed no difference in irANF in swine resuscitated with an isotonic solution (RL) and those resuscitated with a hypertonic solution (HSL). There were significant differences between the two groups in serum sodium and serum osmolarity at RESUS and D_1, but there was no difference between the groups in irANF measured at those times. This suggests that, within the range of our observations (serum sodium: 140–150 mEq/L; serum osmolarity: 285–301 mOsm/L), serum sodium and serum osmolarity do not appear to affect the release of irANF. However, there was only a change of 10% in these parameters during the study and this may have been of insufficient magnitude to affect ANF release. On the other hand, an increase in serum osmolarity of less than 2% can result in a doubling of serum vasopressin levels.[28] If osmolarity is operant in ANF release, the sensitivity of the mechanism appears to be far less than that for AVP release.

Resuscitation normalized the physiologic parameters and returned irANF and REN to BL. By 24 hours after hemorrhage, E and NE had returned to BL and ANF was significantly lower than BL value. This occurred at a time when urine flow and sodium excretion were significantly increased from BL. These results suggest that ANF is not the stimulating factor in the diuresis and natriuresis observed in the postresuscitation period.

TABLE 5. *Comparison of Serum Sodium and Osmolarity and irANF Levels in Animals Resuscitated with RL and HSL (Mean ± SEM)*

	Immediately after Resuscitation		24 Hours after Resuscitation	
	RL	HSL	RL	HSL
SNa (mEq/L)	140 ± 2	150 ± 2*	145 ± 3	153 ± 2†
SOsm (mOsm/L)	286 ± 4	300 ± 4*	284 ± 3	301 ± 5*
ANF (pg/ml)	279 ± 25	308 ± 26	259 ± 32	256 ± 14

Comparisons made between groups (HSL *vs.* RL): * $p < 0.01$; † $p < 0.05$.
SNa = serum sodium concentration.
SOsm = serum osmolarity.

However, our study encompassed only the first 24 hours after hemorrhage, a period marked by a positive sodium and water balance. It is certainly possible that ANF could be involved in the later stages of salt and water excretion, especially when mobilization of fluid is associated with a rise in the CVP. Swine infused with sufficient crystalloid to elevate the CVP 96 hours after the shock experiments had a significant increase in irANF and urine output. It is important to study the potential role of ANF in postresuscitation diuresis further since the salt and water retention after shock and trauma may be detrimental to cardiac and pulmonary function.[29]

Acknowledgments

We thank Marilynn Mastroianni for preparing the manuscript and tables and James Hogan for his assistance in the preparation, care, and humane treatment of the animals. We are also indebted to Paul Shragg and the CRC CLINFO Computer System (NIH grant RR 00827) for assistance in analyzing the data.

Neuroendocrine (Merkel Cell) Carcinoma of the Skin

Its Natural History, Diagnosis, and Treatment

CHARLES L. HITCHCOCK, M.D., PH.D.,* KIRBY I. BLAND, M.D.,† ROBERT G. LANEY III, M.D.,† DAISY FRANZINI, M.D.,*

Over 400 cases of neuroendocrine (Merkel cell) carcinoma of the skin (NCS) have been reported. This tumor continues to pose problems in diagnosis and effective treatment for physicians unfamiliar with its biological characteristics. Reported here are five additional cases of NCS and the literature for this rare neoplasm is comprehensively reviewed. An early and accurate diagnosis is made possible by combining clinical presentation with results of histologic study, immunoperoxidase staining for neuron-specific enolase (NSE), epithelial membrane antigen (EMA), cytokeratins, and electron microscopy. NCS is an aggressive tumor. Depending on the length of follow-up, up to 40% of tumors locally recur, 55% develop regional nodal metastases, and 36% undergo distant metastasis. Survival is sex, but not age, dependent, with an overall 2-year survival rate of 72% (males 58% *vs.* females 79%). No standard procedure for initial and/or follow-up treatment for NCS exists. The authors recommend that NCS be treated, whenever possible, using the same rationale as applied for the treatment of squamous cell carcinoma of the skin.

IN 1972, TOKER COINED THE TERM "trabecular carcinoma" to describe a poorly differentiated carcinoma of the dermis and subcutaneous tissue identified in five elderly people.[1] To date, over 400 cases of this primary cutaneous neoplasm have been reported under a variety of terms[2–65] that include: neuroendocrine carcinoma of skin,[6,8] Merkel cell tumor or carcinoma,[9] primary small-cell carcinoma of the skin,[10] APUDoma,[11] extra-pulmonary carcinoma of the skin,[49] and endocrine carcinoma of the skin.[50] The term neuroendocrine carcinoma of the skin (NCS) is preferable and describes the histologic, ultrastructural, and immunohistochemical features of the tumor without ascribing a cell of origin.

Although the clinicopathologic features of NCS have been widely described, this tumor continues to be a problem for clinicians unfamiliar with its biological characteristics. The natural history of NCS remains to be defined. Currently, these tumors are considered to be aggressive with a variable prognosis.[50] They are difficult to treat effectively and few guidelines for their treatment have been reported.[46,50,55,60,65]

This study was designed to examine the clinical and pathologic differential diagnostic criteria and biological behavior of NCS. Five additional cases of this tumor are described in conjunction with an extensive review of the literature. This review addresses further the clinical presentation, behavior, and response to therapy of this neoplasm.

Methods

Five cases of NCS have been seen at the University of Florida's Shands Teaching Hospital (STH) and the Gainesville VA Medical Center (GVAMC) since 1982. Three were seen as a primary lesion, whereas the remaining two were referred to the Department of Surgery for further treatment. All charts were reviewed and the clinical data verified.

Tissue was fixed in 10% neutral buffered formalin and processed for routine histologic evaluation. Tissue was processed by standard procedures for ultrastructural analysis. Formalin-fixed, 5-μm paraffin sections of tumor and appropriate controls were used for immunoperoxidase staining. The avidin-biotin staining method

of Hsu[66] was used in conjunction with antibodies to neuron-specific enolase (NSE), epithelial membrane antigen (EMA), cytokeratin (CK), and neurofilaments (NF) for staining of representative sections from each tumor.

Results

Case 1

A 52-year-old white man presented to the GVAMC with a 2-month history of a firm, painful, mass in the axillary tail of the left breast. Currettings were interpreted as consistent with infiltrating ductal carcinoma. One month later, he had a radical left mastectomy for two discrete 2.5-cm tumor nodules and an excisional biopsy of a contralateral, subcutaneous parasternal mass. Histologic and ultrastructural studies were consistent with NCS. In 2 months, regional and distant nodal metastases were observed. Multiple nodal, cerebral, and cutaneous lesions, but no lung lesions, were noted on CT scan at 3 months. He received palliative whole brain radiation therapy (3000 rads) and three courses of chemotherapy consisting of cyclophosphamide (1000 mg/m^2), doxorubicin (50 mg/m^2), and vincristine (2 mg). Initial tumor regression followed, with subcutaneous and cerebral recurrence occurring at 10 months. The patient died with tumor 12 months after his initial presentation.

Case 2

A 70-year-old white man with a 3-year history of well-differentiated lymphoma treated with cyclophosphamide and prednisone presented to STH with a 6-month history of a 3.5-cm firm, cutaneous nodule of the left thigh. The nodule was excised and interpreted as an "undifferentiated malignant neoplasm." Two months later he was diagnosed as having recurrent lymphoma and began a 28-month course of chemotherapy consisting of prednisone (80 mg) and chlorambucil (50 mg). At 17 months he had a 1.5-cm subcutaneous nodule on the left thigh, which was excised and interpreted as being consistent with NCS; wide local excision of the thigh lesion was performed with no residual tumor noted. The patient is currently alive at 36 months with no evidence of disease (NED).

Case 3

A 62-year-old white woman presented to a local physician with a subcutaneous lesion of unknown duration on the left buttock that had been incised and drained. The lesion enlarged and was excised at 4 months, with pathologic characteristics consistent with NCS. At 5 months she was observed to have left inguinal adenopathy, as well as recurrence at the previous excision site. At 6 months she was referred to STH for treatment, and a superficial inguinal node dissection and a wide excision of the original recurrent buttock lesion were completed. NCS was identified in specimens from both sites. She was subsequently treated with radiation therapy to both the inguinal areas (5000 and 6000 rads to the medial and left inguinal regions, respectively) and to the buttock (1000 rads). She is currently alive at 17 months and remains NED.

Case 4

A 67-year-old white man presented to a local physician with an 8-mm subcutaneous nodule of the forehead of 10 months' duration. The findings of an excisional biopsy were interpreted as NCS. Four months later he underwent a superficial right parotidectomy for metastatic tumor. He was subsequently treated at a second hospital with three courses of chemotherapy consisting of cyclophosphamide (750 mg/m^2), CCNU (70 mg/m^2), and methotrexate (15 mg/m^2), with subsequent subjective response. At 9 months he was observed at GVAMC to have an 8.0-cm right neck mass and cervical adenopathy. At 11 months, right parotidectomy and a conservative right neck dissection were completed. Tumor was found in 12 of 20 nodes, in extranodal tissue, and at the margin of resection in several sites. Radiation therapy was given to both the surgical bed (2000 rads) and to the ipsilateral neck (6000 rads). CT-guided biopsies demonstrated abdominal metastatic lesions at 19 months. Chemotherapy consisting of cyclophosphamide (1000 mg/m^2), doxorubicin (45 mg/m^2), and VP-16 (50 mg/m^2) was begun, but the patient was lost to follow-up after one course. He was readmitted to GVAMC at 26 months with a recurrent abdominal mass and restarted on the previous chemotherapy regimen with marked shrinkage in the tumor mass. He is currently alive at 28 months with no clinical evidence of tumor.

Case 5

An 82-year-old white man presented to STH with a 2-cm, rapidly enlarging, subcutaneous gluteal mass of 5 months' duration. The findings of the initial biopsy were interpreted as an "unusual primary carcinoma consistent with Merkel cell carcinoma." The tumor was widely excised at 1 month and diagnosed as NCS. At 8 months, regional adenopathy developed and the patient underwent a right superficial inguinal node dissection. Metastatic tumor was found in 5 of 11 nodes as well as in an extranodal soft tissue. No further treatment was initiated at that time. Eighteen months after presentation, lytic lesions of the T7 vertebrae were apparent, for which he received 3000 rads of local radiation therapy. He is currently alive at 27 months with metastatic disease.

Our five patients had a characteristic presentation of NCS. They were elderly patients, ranging from 52 to 82 years of age, who had a history of a slowly enlarging, firm skin nodule. The tumors ranged from 0.8 cm to 3 cm in maximal dimension, and were located on the lower extremities in three cases, and one each on the chest and the face. Results of the initial histologic interpretation of these lesions demonstrate the necessity of using additional diagnostic techniques. The initial lesion in two cases was misinterpreted; with the correct diagnosis of NCS being made on subsequent review. Contributory is the fact that NCS has a spectrum of histologic appearances that range from lymphomas, invasive carcinoma, and other small round cell tumors. In general, NCS was noted to be a monomorphic, nonorganoid, small round cell tumor arising in the dermis (Fig. 1). Electron microscopic studies demonstrated the presence of electron-dense, neurosecretory type granules in the cytoplasm and cell processes, as well as collections of intermediate filaments and immature cell junctions (Fig. 2). Immunoperoxidase staining for NSE, EMA, and cytokeratins demonstrated both intra- and intertumor variations. NSE was consistently demonstrated, whereas staining of paraffin sections for NF was very inconsistent.

The clinical behavior of NCS in these five patients was consistent with that of a biologically aggressive tumor. Local recurrence was observed in four patients (cases

1–4) with an average of 6 months (range: 1–17 months) from the time of presentation. Regional nodal metastases developed in case 5 without prior local recurrence, whereas cases 1, 3 and 4 progressed to regional nodal involvement 1–9 months after diagnosis. Distant metastasis occurred in three of the four patients (cases 1, 4,

Lower Extremities	30.2%
Trunk	3.8%
Multiple	1.5%

and 5) with nodal involvement 3–19 months (mean: 13.3 months) after initial presentation. Only case 1 has died of tumor.

Discussion

Neuroendocrine carcinoma of the skin is an infrequent, but by no means rare, primary cutaneous neoplasm. To date, the natural history of NCS remains undefined. The reason for this deficiency is best explained by the fact that previous studies have focused on the pathologic rather than the clinical and/or the biological features of the tumor. The elucidation of these features will aid pathologists and clinicians to initiate both a prompt diagnosis and effective therapy. We have added five additional cases to the over 400 cases of NCS reported in the literature,[1-65] and have undertaken a comprehensive review of the reported cases. Our purpose is to better comprehend NCS's biological behavior, to delineate its essential diagnostic features, and to propose guidelines for its treatment.

TABLE 2. *Clinical Behavior of Neuroendocrine Carcinoma of Skin*

	No. of Patients (%)
Local recurrence	
Patients with ≥6 months F/U*	80/220 (40.0)
Multiple 30/88 (34.1%) (range 2–9×)	
Time from initial diagnosis to first local recurrence: 1–54 months (mean: 10.1 months)	
Regional lymph node metastasis	
All patients	
At presentation	31/254 (12.2)
Following initial diagnosis	86/187 (46.0)
Patients with ≥12 months F/U	107/193 (55.4)
Time from initial diagnosis to nodal metastasis: 1–202 months (mean: 13.4 months)	
Distant metastasis	
All patients	82/226 (36.3)
Multiple sites	10/82 (12.2)
Patients with ≥24 months F/U	73/148 (49.3)
Time from initial diagnosis to distant metastasis: 11 days to 96 months (mean: 18.3 months F/U)	

F/U = follow-up.

NCS is primarily a lesion of sun-exposed skin of the elderly (Table 1). Essentially 50% of reported NCS lesions are located on the head and neck, whereas less than 5% involve the skin of the trunk. Patient age is reported to vary from 15 to 97 years with a mean of 67.9 years. There is no apparent sexual predominance as has been reported previously.[23,25,32,41,50,59,60,65] Patients often have a history of a slowly enlarging, pink to violaceous plaque or nodular subcutaneous lesion that suddenly rapidly increases in size.

NCS behaves as an aggressive tumor with local recurrence and metastases as common features (Table 2). Forty per cent of the patients who were followed a minimum of 6 months or who died before this time, exhibited local recurrence, with close to one third having multiple recurrences. The mean time from diagnosis to first local recurrence was 10.1 months in 220 cases (range: 1–54 months). Approximately 75% (53 of 71) of reviewed cases with local recurrence and 6 months or more follow-up exhibited disease progression with regional nodal and/or distant metastasis. Of these 53 patients, 29 (55%) died of tumor, whereas 30% were alive at the time of publication (Table 3).

NCS has a propensity for early involvement of regional lymphatics (Table 2). Regional nodal metastases were evident in 55% of the reported patients who were followed for 12 months or more, or who died before this time. Adenopathy was noted from 1 to 202 months (mean: 13.4 months) after initial diagnosis. Nodal involvement at the time of initial presentation was observed for 31 of 254 patients (12.2%). A total of 37 of 74 (50%) patients with regional nodal metastasis subsequently developed distant metastases, of which 27 (73%) died of the disease. Only six of 74 (16.2%) reported patients have died of tumor without further metastatic disease developing (Table 3).

Distant metastases occurred in 82 of 226 (36.3%) reported cases of NCS; 10 of 82 (12.2%) exhibited multiple metastases (Table 2). Of the 148 patients with a reported follow-up of 24 months or greater, or who died before this interval, 73 (49.3%) had distant metastatic disease. The mean time from initial diagnosis to discovery of metastatic tumor was 18.3 months (range: 11 days to 96 months). Sites for distant metastatic disease in order of decreasing frequency include: lymphatics, liver, bone (including vertebrae, as in case 5), brain (as in case 1), lung, and skin. Retroperitoneal lymph nodes (as in case 1) are the most common site for distant nodal spread. Involvement of the parotid gland (as in case 4) is consid-

* Literature 1: excludes patients reported by Silva et al.[50]

† Literature 2: excludes 18 patients reported by Silva et al.[50] and excludes LTFU, and DOC patients and alive includes AWT patients.

LTFU = lost to follow-up; AWT = alive with tumor; DOC = dead from other causes than tumor; DOD = dead of disease; F/U = follow-up; LN = lymph node; Mets = metastasis.

ered to be by direct extension rather than by metastasis.[60]

Death from tumor has been reported to vary from 67% to 74% (Table 3) for patients with distant metastases. For 45 patients in whom precise clinical information was available, death from tumor occurred within an average of 6.2 months from diagnosis of widespread metastatic disease.

The overall prognosis for patients with NCS has been reported to vary. A Kaplan-Meier survival analysis of cases, both those reported and including our five cases, is seen in Figure 3. Overall survival rates are: 1-year, 88%; 2-year, 72%; and approximately 55% at 3 years. The lack of sufficient numbers of patients with 3 or more years of follow-up precludes accurate determination of survival. There was no significant correlation between survival and patient age. Female survival was significantly greater ($p = 0.0069$ Wilcoxon) than that for males. Two-year and 3-year survival rates for males and females were, respectively, 58% *versus* 79.4% and 35.6% *versus* 67.6%.

The metastatic potential of NCS mandates that an early and accurate diagnosis be made by the clinician and the pathologist. The majority of these lesions arise in the dermis and extend into the subcutaneous fat. The spectrum of histology of NCS can make a definitive diagnosis difficult. Goepfert et al.[46] reported that misdiagnosis was as great as 66% when light microscopy was used alone. The differential diagnosis for NCS includes: metastatic oat cell carcinoma, lymphoma, amelanotic melanoma, and adnexal tumors. The correct diagnosis is best derived from a combination of a thorough clinical evaluation, coupled with light and electron microscopy with a defined panel of immunoperoxidase stains. Three principle ultrastructural features aid in differentiating NCS from these other tumors: 75–200-nm electron-dense neurosecretory type granules, paranuclear bundles of intermediate filaments (fibrous bundles),[60] and primitive (nondesmosomal) junctional complexes (Fig. 2). These features are not associated with other primary cutaneous tumors. Immunoperoxidase staining for NSE, EMA, and cytokeratins is highly recommended. Monoclonal antibody to the leukocyte common antigen (LCA) can be used on paraffin sections to rule out a diagnosis of lymphoma.

Treatment guidelines are designed and implemented after thorough clinical evaluation and regular follow-up. The following guidelines for the clinical management of

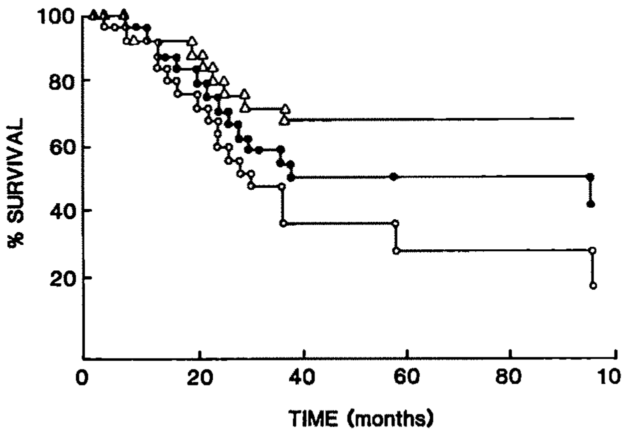

FIG. 3. Kaplan-Meier survival analysis of 172 patients with neuroendocrine carcinoma of the skin. Females have a significantly greater ($p < 0.007$) survival at 24 and 36 months compared with males.

NCS are based on our experiences as well as those of others reported in the literature.

Among reported cases, surgical treatment for primary NCS has varied from incision and drainage to wide excision. Local recurrences arise primarily from an inadequate excision of the primary tumor (the tumor approximates or contaminates the margins of resection). Reported tumors vary from 4 mm to 12 cm, with two thirds being 2 cm or less in greatest dimension. Thus, the majority of the lesions are amenable to excision. We and others[41,46,50,60,65] recommend a wide excision (2-3-cm margin) of the primary lesion be performed with similar techniques implemented for squamous cell carcinoma of the skin.

Prophylactic nodal dissection has not been completed on a routine basis. Silva et al.[50] recommended nodal dissection be performed if the primary tumor was 2 cm or greater, if there is a high mitotic rate (10 HPF), or if the hyperchromatic cell pattern predominates. Relative to head and neck lesions, these authors recommend nodal dissection be performed when the primary tumor is situated in proximity to the nodal regions.[46] We concur that a therapeutic regional nodal dissection be performed for adenopathy as well as for the presence of vascular invasion. In addition, all patients with a primary tumor of the head and neck should undergo radical neck dissection as Goepfert et al.[46] have reported a 75% failure rate for untreated nodes. Patients with midline head and neck primary tumors should undergo bilateral radical neck dissection, which may be staged. Should prophylactic regional node dissection not be initiated, careful patient education and interval physician examination are prudent.

NCS is a radiosensitive tumor.[50,65] Irradiation has been used prophylactically as well as for recurrent and metastatic lesions. Silva and co-workers[46,50] consider that radiation therapy failures are "geographic misses" due to inadequate field margins. They recommend prophylactic radiation therapy be used to reduce local recurrence and/or metastasis. We recommend that radiation therapy be completed in the following cases: (1) where the tumor approximates the margin of resection, (2) when there is histologic evidence of vascular space involvement, and/or (3) if nodal metastasis is present. In these clinical settings, radiation portals should include the tumor bed and the lymphatics in transit. Silva et al.[50] have reported no radiation therapy failures for doses ≥ 4500 rads delivered over 5 weeks. Until a dose-response curve is available for NCS, we believe that equivalent irradiation dosage should be administered.

Chemotherapy has been used in the treatment of NCS where there has been an absence of local tumor control. To date, a wide variety of cytotoxic agents have been used and include: VP-16, cisplatin, CCNU, methotrexate, vincristine, doxorubicin, and cyclophosphamide. These regimens have been applied with variable objective response being reported. Kroll and Toker[20] note that tumor regression with chemotherapy was rapid but that recurrence occurred within 6–12 months. Other studies have reported similar results.[50,55,60] The infrequent incidence of the tumor precludes a prospective study for determination of the superior drug regimen. We are currently using cyclophosphamide, doxorubicin, and VP-16 to treat systemic disease in one of our patients (case 4). We and others[50] recommend that the same regimen used for the treatment of oat cell carcinoma should be considered for the treatment of systemic NCS.

Lymphoid Subpopulation Changes after Thermal Injury and Thermal Injury with Infection in an Experimental Model

DAVID G. BURLESON, PH.D., ARTHUR D. MASON, JR., M.D., and BASIL A. PRUITT, JR., M.D.

Subpopulation analysis of peripheral blood lymphocytes is a frequently used measure of immunocompetence. Yet, little is known about the lymphocyte subpopulations in the circulation and lymphoid organs after severe trauma. Blood, spleen, and lymph node (LN) subpopulations were compared in a rat model of burn injury (B) and burn injury with infection (BI). B and BI rats received 30% total body surface scald burns. Infection was induced by seeding wounds with *Pseudomonas aeruginosa.* Subpopulations were identified by flow cytometry 48 hours after burn. Helper lymphocytes were selectively depleted from the circulation of BI but not B animals, which caused the ratio of helper to suppressor cells (HSR) in BI animals to decrease significantly compared with the unburned controls. Both LN helper and suppressor cells were decreased in BI animals and the HSR was unchanged, but a selective reduction in suppressor cells in B LN increased the HSR relative to unburned controls. Spleen subpopulations were unchanged for both B and BI groups. Subpopulation changes after trauma and infection were different for each tissue examined.

From the U.S. Army Institute of Surgical Research, Fort Sam Houston, Texas

INFECTION STILL ACCOUNTS for a large fraction of the mortality observed in patients with large burns.[1,2] The susceptibility of burned patients to infection by organisms that are ordinarily nonpathogenic suggests an acquired defect in host defense mechanisms. Many aspects of host defense have been examined in an attempt to define this underlying defect, and many cellular and humoral aspects of host defense have been found to be abnormal.[3-8] However, none of the abnormalities described can be pinpointed as the cause of the observed increased susceptibility to infection.

Several conditions that present clinically with increased risk of infection are accompanied by relative changes in lymphocyte subpopulations,[9] usually described as a decrease in the ratio of T-helper to T-suppressor cells (HSR) in the circulation. The shift in this ratio may reflect a change in the balance between immune stimulation and suppression. An inappropriate change in this regulatory balance could lead to decreased resistance to infection.

Lymphocyte subpopulation changes are usually measured in lymphocyte samples from peripheral blood. Peripheral blood lymphocytes are a relatively small fraction of the total lymphocyte pool and may not present a valid picture of the immunological state of the individual. This mobile pool of cells might be expected to fluctuate more widely in response to stress or infection than the lymphocyte populations in the relatively immobile lymphoid tissues. Additionally, the accuracy of measurements of peripheral blood lymphoid cells can be impaired by atypical leukocyte populations, which are often found in the circulation of trauma victims several days after severe injury.[10] Sampling of a greater range of lymphocyte sources, such as spleen and lymph nodes, may give a more general picture of immunocompetence than assessment of peripheral blood alone.

We have analyzed the changes in lymphoid cell populations that occur after either burn injury or burn injury complicated with infection in a well-defined burn and burn-infection model.[11] The results show that relative increases in the proportion of suppressor lymphocytes relative to helper lymphocytes (decreases in the HSR) do

not occur in the blood, spleen, or lymph nodes of infection-susceptible but uninfected burned animals. Decreased HSR was observed only in the blood of burned animals with infection.

Methods

Male albino Sprague-Dawley rats (300–400 g) were randomly assigned to one of three groups: an unburned control group, a burned group, or a burned group with infection. All rats were anesthetized with pentobarbital (IP, 1 mg/100 g body weight), and those in the burned groups were shaved, placed in a plastic mold that defined the burn surface area, and subjected to a 30% total body surface full-thickness burn by 10-second immersion in boiling water.[11] Infection was induced by placing 1 ml of a 16-hour broth culture containing approximately 10^8 *Pseudomonas aeruginosa* (strain 59-1244) on the burn wound within 1 hour of scalding.[12] At sacrifice, 48 hours after infection, the rats were anesthetized with pentobarbital and exsanguinated by opening the body cavity and bleeding from the hepatic vein. Subsequently, blood, spleen, and mesenteric lymph nodes were taken for cell analysis.

Peripheral blood leukocyte counts were made using a Coulter Counter (model ZM, Coulter Electronics, Hialeah, FL), and differential analyses were performed on blood smears. Spleen cells were obtained by disrupting the spleen and passing the cell suspension through a loosely packed cotton wool column to remove debris. The lymphoid cells from blood and spleen were separated from other cells by centrifugation over a Ficoll-Hypaque density gradient.

Lymph nodes were trimmed of excess tissue and minced with scissors over a 60-mesh stainless steel screen. The cells passing through the screen were passed through a loosely packed cotton wool column to screen out extraneous pieces of tissue. More than 95% of the lymph node cells obtained in this manner were lymphocytes and these cells were used without further purification. The isolated cells from each tissue were washed and samples of the cells were used to prepare slides for differential analysis. The remaining cells were stained with appropriate lymphocyte mouse monoclonal reagents obtained from Pel-Freez (Roger, AZ). The monoclonal reagents attached to the cell surface were further bound with affinity-purified, fluorescein-labeled goat anti-mouse IgG (Fab2′ fragments) as a second step reagent.

The fluorescently stained cells were then analyzed, using a Fluorescence Activated Cell Sorter, model 400 (Becton Dickinson, Mountain View, CA), modified by addition of a 90-degree light scatter PMT and a consort 40 data analysis system. For each sample, 5000 cells were analyzed and the numbers of cells fluorescently stained with T lymphocyte (W3/13), suppressor/cytotoxic (OX-8), or helper/inducer (W3/25) reagent were determined. A negative control using a monoclonal antibody to human T cells (which had no specificity for rat cells) was run with each cell preparation to determine an appropriate cutoff to distinguish negative from positive cells. The positive cutoff was set at a point defining the upper 2% or less of the background control and the number of background control cells beyond the cutoff was subtracted from each sample. Contamination by nonlymphoid cells was monitored by analyzing forward and 90-degree scattered light. Those cells with light scatter intensity not typical of normal lymphocytes were not analyzed (gated).

The proportion of the positive cells for each of the subsets were compared among the three animal groups. Statistical analysis consisted of a pairwise analysis of means (t-test) with a Bonnferroni adjustment, performed on a VAX 11/780 (Digital Equipment Corporation, Maynard, MA) using program P7D (BMDP Statistical Software, Los Angeles, CA).

Results

Light scatter analyses of cells from each tissue were compared with morphologic analyses of cells on Wright's stained preparations to determine the effectiveness of the light scatter analysis as a measure of nonlymphoid cell contamination. Ficoll-Hypaque purified blood cells from burned animals showed no significant change in either light scatter characteristics or Wright's stain morphologic characteristics when compared with unburned controls (Table 1). Blood cells from burned animals with infection, however, showed a significant decrease in the proportion of cells ($p < 0.01$) with scatter characteristics typical of normal lymphocytes. This decrease correlated with a decrease in the proportion of cells with lymphocyte morphologic characteristics and an increase in the proportion of cells with morphologic characteristics of immature granulocytes or atypical mononuclear cells. There was no significant change from control in the light scatter characteristics or cellular morphologic characteristics of lymph node or spleen cells from burned or burned animals with infection.

Surface antigen analysis was performed on blood mononuclear cells that exhibited light scatter typical of normal lymphocytes (Fig. 1). The proportion of helper lymphocytes was decreased, whereas suppressor/cytotoxic lymphocytes were increased in the blood of burned rats with infection relative to control, but not in the blood of animals subjected to burn alone. This relative shift in subpopulations caused the HSR of circulating lymphocytes to decrease significantly ($p < 0.01$) in burned animals with infection compared with controls. Lymph node cells from burned animals with infection (Fig. 2) consisted of a significantly smaller proportion of T-lymphocytes (Pan-T) than uninfected animals as well

TABLE 1. *Differential Analysis of Ficoll-Hypaque Preparations by Light Scatter and Wright's Stain Morphology**

Cell Source/Group	Cells ± SD (% in "Lymphocyte" Gate)	Significance Level	% Lymphocytes (Wright's Stain)
Blood			
Control	77.6 ± 11.01	ns	91.0 ± 9.9
Burned	73.8 ± 8.8	ns	87.0 ± 11.4
Burned-infected	56.4 ± 16.3	(vs. control $p < 0.01$)	74.9 ± 16.4
Spleen			
Control	66.2 ± 12.0	ns	99.5 ± 1.0
Burned	69.2 ± 13.3	ns	98.7 ± 1.8
Burned-infected	61.3 ± 18.7	ns	95.8 ± 11.4
Lymph node			
Control	91.8 ± 4.9	ns	100 ± 0
Burned	89.9 ± 7.5	ns	99.9 ± 0.1
Burned-infected	92.0 ± 8.1	ns	99.8 ± 0.5

* Cells were analyzed for light scatter characteristics by flow cytometry and the number of cells falling within the lymphocyte "window" determined. A small aliquot containing approximately 10^5 cells was used to make a cytocentrifuge slide that was stained using Wright's stain and examined for the relative number of lymphoid and nonlymphoid cells under light microscopy.

as reduced proportions of both helper and suppressor lymphocytes. In burned uninfected animals the proportion of suppressor lymphocytes was lower than that of control animals, but the proportion of helper and Pan-T positive cells was not significantly different. Spleen cells from infected animals contained a small subpopulation of cells (5–10% of the total) that bound monoclonal antibody control reagents. Control reagents had the same mouse immunoglobulin isotype as the monoclonal reagents, but had no reactivity to rat cells. Therefore, the data depicted for spleen cells (Fig. 3) from infected animals may overestimate the true value for one or more of these populations by 5–10%. However, there was no significant difference in any of the three T-lymphocyte subpopulations or the HSR in the spleens of burned or burned animals with infection compared with unburned controls.

A summary of the HSR determined for each tissue is depicted in Figure 4. Infected animals show more variation in the ratio than the other groups, having a decreased ratio in blood but an increased (although statistically not significant) ratio in lymph node. The HSR increased in the lymph node even though both helper and suppressor/cytotoxic subsets decreased, because there was a disproportionate decrease in suppressor cells. The decrease in suppressor cells present in the lymph nodes of burned animals caused an increase in the HSR. This was the only difference in any of the lymphocyte subpopulations induced by the burn injury alone. The HSR determined in spleen cells was not significantly different from control in either of the experi-

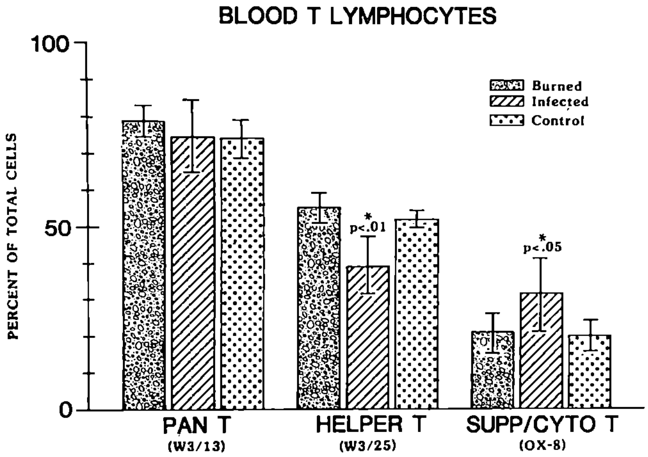

FIG. 1. The proportion of Ficoll-Hypaque purified blood cells positive for three T-lymphocyte surface antigens. Cells from burned and burned-infected and control rats were analyzed by flow cytometry for each of the three major T-lymphocyte surface antigens. The number of cells staining positively for each antigen is expressed as the mean percentage of total cells analyzed ± SD (N = 10).

mental groups even though the number of lymphoid cells in the spleen was decreased sharply in the infected animals (data not shown).

The changes induced by burn injury alone and burn injury with infection are summarized in Table 2. A decrease in the suppressor subpopulation in the lymph nodes was the only significant subpopulation change for the infection-susceptible, but uninfected, burned animals. In the infected animals, proportional decreases were observed in all lymph node T cell subpopulations. In the blood of infected animals, the proportion of helper lymphocytes decreased, whereas the proportion of suppressor lymphocytes increased. The only changes in HSR were a decrease in the blood of infected animals and an increase in the lymph node of burned animals without infection.

Discussion

Other studies have been interpreted as showing that burn injury increases the relative proportion of suppressor cells (decreases HSR) in the burned host. It has been implied that such a shift in subpopulations decreases the capacity of the host to mount an immune response and thereby decreases resistance to infection. It is important to note that the changes in HSR are relative and that an absolute increase in the number of suppressor cells has not been reported. Using a mouse model, Zapata-Sirvent and Hansbrough[13] found a decreased spleen cell HSR to be correlated with decreased skin hypersensitivity to dinitrofluorobenzene 10–14 days after thermal injury. In a later study[14] Zapata-Sirvent et al. described a correlation between decreased hypersensitivity and mortality after infection induced by cecal ligation and puncture. In a rat burn infection model we have found that a decrease in the HSR in peripheral blood occurred only in the presence of infection and not as a consequence of injury *per se.*[15] In human burn patients a correlation between a decreased HSR and increased susceptibility to infections has been reported in patients with large burns by McIrvine et al. and Antonacci et al.[8,16] They reported decreased HSR in patients with burns covering more than 30% of the total body surface. In one study,[8] decreased helper/suppressor ratios occurring more than 14 days after burn were positively correlated with the occurrence of fatal sepsis. As in most clinical studies it is difficult to determine whether lymphocyte subpopulation changes are related to the cause of infection or are an effect of infection.

In the current study, the blood HSR measured 48 hours after injury and infection was decreased in infected animals. In uninfected burned animals, however, the HSR was not significantly different from control. Since infected animals have decreased circulating lymphocytes,[15] the change in proportion of helper and sup-

pressor cells due to infection was related to depletion of helper cells from the circulation, rather than any increase in suppressor cells. The observed decrease in blood HSR appears after rather than before infection. Susceptibility to infection after injury cannot be attributed to any relative increase in the number of suppressor/cytotoxic cells in the blood.

There was no decrease in the HSR in the mesenteric lymph nodes or spleens of the infected animals (Table 2) as was observed in blood. The total number of lymphocytes in the lymph nodes and spleen is much greater than in peripheral blood. The changes seen in blood subpopulations may represent transient depletion of selected subsets of lymphocytes as they migrate from the peripheral circulation. The subsets of the lymphocytes in the circulation are apparently subject to wider fluctuations in response to infection than those that occur in the total lymphoid population. The lack of uniformity among subpopulation shifts in the different tissues demonstrates that each of the lymphoid tissues acts, to some extent, as an individual compartment rather than as part of a common reservoir of lymphoid cells.

Although relative changes in lymphocyte subpopulations do not appear to accompany the increased susceptibility to infection after burn injury, subpopulation analysis of peripheral blood may have clinical use as an indicator of existent sepsis, since HSR appears sensitive to the presence of infection. That possibility awaits further study. Since the immune response results from a complex interaction among several subpopulations of cells, measurement of cell function rather than simple enumeration of subpopulations is more likely to yield information about the nature of the defects in host defense after burn injury.

Congenital Angiodysplasia of the Superficial Venous System of the Lower Extremities in Children

ARKADI GORENSTEIN, M.D., SCHMUEL KATZ, M.D., and MEDAD SCHILLER, M.D.

From the Department of Pediatric Surgery, Hadassah University Medical Center, Jerusalem, Israel

Congenital angiodysplasia of the superficial venous system (SVS) of the lower extremities was diagnosed in 24 children 3–15 years of age. Nine patients presented with painful swelling in the affected limb. Venectasia and spongy venous masses were the main morphologic changes in the current series. Selective ascending functional phlebography and superficial phlebography were used to assess the anatomic extension of the lesions and to evaluate the functional status of the involved extremity: 14 patients had only SVS angiodysplasia, in 10 patients additional pathologic features of the deep veins (DV) were found. Venous reflux was demonstrated in 16 patients and significant venous insufficiency was detected in five patients. The patients were classified into three groups according to the severity of the disease: mild (11 patients), moderate (8 patients), and severe (5 patients). The prognostic and the long-term outcome of surgical treatment can be predicted by the depth and the extension of the angiodysplastic lesions.

CONGENITAL VASCULAR MALFORMATIONS of the lower extremities are relatively rare. The variability of their clinical and radiologic presentation may create some confusion in the diagnosis and raises controversy in the therapeutic approach. The prognostic outcome of these lesions is frequently unclear. Superficial proliferative vascular lesions with increased mytotic activity are defined as hemangioma.[1-3] Vascular lesions that grow with the child and show normal endothelial mytotic activity are called malformations. Venous malformations, venous angiodysplasia, were classified by Malan and Puglionisi,[4] and their radiologic features were clearly defined.[3,5,6]

The venous anomalies of the lower extremities are divided into two groups: (1) deep venous (DV) malformations involving the central veins, which are the main draining pathways of the lower extremity; and (2) superficial venous system (SVS) malformations involving the superficial venous pathways rather than the deep venous trunks.

This study presents our experience with congenital angiodysplasia of the SVS of the lower extremities in children. The therapy of these unusual lesions has been based on a diagnostic approach that delineates the morphologic changes and assesses the degree of venous dysfunction.

Materials and Methods

Eighty-five children 2–15 years of age with congenital and acquired vascular disorders of the lower extremities underwent a complete physical examination, including measurements of leg length and circumference in both the recumbent and standing positions.

The main vessels were examined by Doppler ultrasonography. The partial oxygen tension of the venous blood was determined to identify arteriovenous fistulas. Elongation or shortening of the involved limb and soft tissue changes such as phleboliths and hemangiomas were demonstrated by plain x-ray films.

The patients underwent selective ascending functional phlebography. The posterior tibial vascular bundle located behind the medial malleolus was exposed under local anesthesia, and the vein was cannulated. Hypaque 50% (1 ml/kg to a maximum of 20 ml) was rapidly injected without a tourniquet. Three radiographs of the lower extremity were obtained while the patient was standing and the leg was internally rotated: immediately after injection, 30–40 seconds later after active functional stress consisting of lifting the heel four times, and 3 minutes after the first radiograph. Normally, the contrast material is completely cleared from the venous system in 3 minutes. The degree of venous

insufficiency is determined by the amount and location of the contrast material remaining in the lower extremity on the last radiograph. In children younger than 3 years, phlebography was performed under general anesthesia in the recumbent position, and functional parameters could not be measured. Using selective ascending functional phlebography, we define three degrees of venous insufficiency: (1) first degree: retention of no more than 50% of the contrast material in either superficial or deep venous system, (2) second degree: retention of less than 50% in both systems simultaneously, and (3) third degree: retention of more than 50% of the contrast material in both venous systems.[7]

In addition, 12 patients underwent superficial phlebography. Hypaque 50% was injected rapidly by hand without a tourniquet into one of the subcutaneous veins of the foot. Radiographs were obtained with the patient at a 45-degree oblique position.

The severity of the disease was graded as the following: (1) mild, cosmetic defect; (2) moderate, cosmetic defect and local pain; and (3) severe, painful and swollen leg, muscle atrophy, hemarthrosis with significant disability.

Twenty-three operations were performed in 18 patients (see Table 4).

Results

Congenital angiodysplasia of the superficial venous system was diagnosed in 24 children (15 girls and 9 boys). The age range was 3–15 years and the median age was 9 years. All patients had unilateral pathology (left, 14; right, 10).

Clinical Examination

The main clinical findings are summarized in Table 1. Nine patients had pain in the affected limb while standing or walking for 5–10 minutes. In most patients, the pain was localized to the lesion. In a few children, the pain extended distally from the lesion to the foot and was accompanied by remarkable swelling. There was no significant difference in length of the extremities. However, 11 patients showed an increase in circumference of the involved leg ranging from 2 to 7 cm. None of the patients had clinical or sonographic signs of arteriovenous malformations. Intracuticular lesions ranged from a typical "port wine stain" to bluish discoloration with some skin irregularity due to abnormal venous dilatation of the deeper layers of the skin.

The subcutaneous lesions consisted of either a single dilated vein or conglomeration of dilated and tortuous veins with or without spongy venous masses. Phleboliths were occasionally palpated in the collapsed spongy lesions. Subfascial angiodysplastic malformation should be suspected in patients where leg circumference decreases when measured in the upright *versus* recumbent position. This is due to the presence of collapsed angiodyspastic lesions and muscle atrophy.

Radiological Findings

Selective functional ascending phlebography and superficial phlebography were used to assess the anatomic and functional disorders in SVS angiodysplasia.

Based on these examinations, the patients were divided into two groups. In 14 children (group A), selective ascending functional phlebography demonstrated normal drainage *via* deep veins of the thigh and calf (Table 2), with either no reflux in half of them (Fig. 1A) or mild reflux in the rest (Fig. 2A). In five patients of this group, venous insufficiency of first or second degree was found. Superficial angiodysplastic lesions in these patients were demonstrated only by superficial phlebography. Lesions ranged from a persistent embryonal veins (Fig. 2B) to large, spongy malformations (Fig. 1B). In the other 10 patients (group B), abnormal deep venous system was demonstrated (Table 3); saccular an-

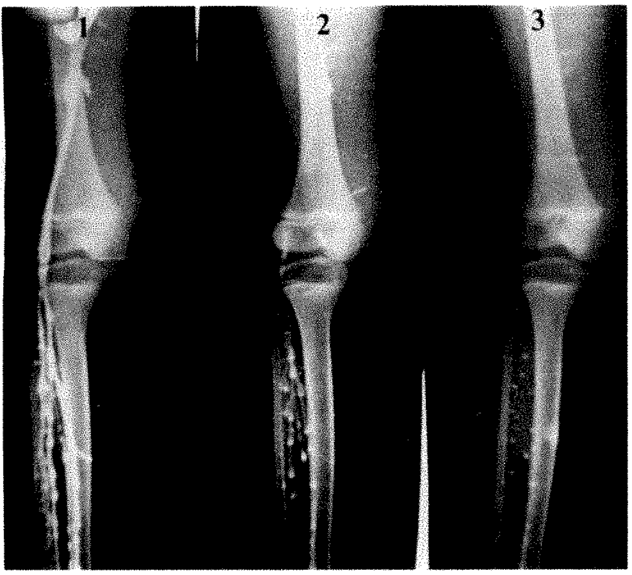

FIG. 1A. Selective ascending functional phlebography in a 9-year-old girl demonstrates normal deep veins of affected lower leg with no venous insufficiency (1) immediately after injection, (2) 40 seconds after injection, and (3) note the contrast material completely disappeared 3 minutes later.

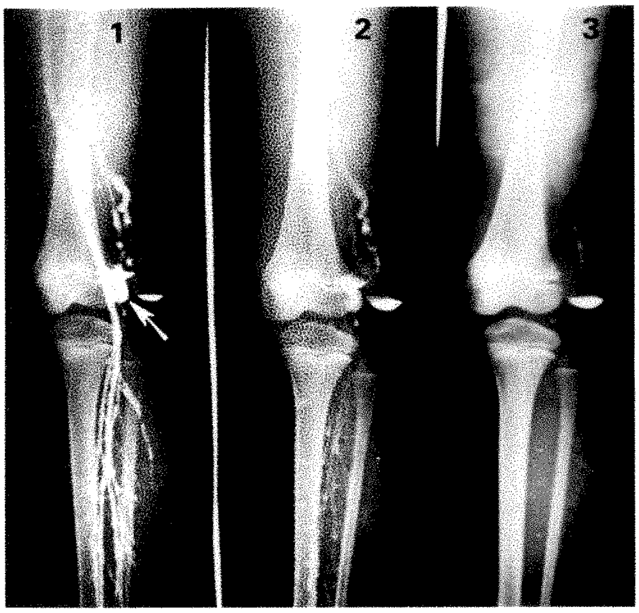

FIG. 2A. Selective ascending functional phlebography in a 5-year-old girl demonstrates reflux through a typical short communicant (arrow) from normal deep veins into a peripheral venous malformation: 0, 40 seconds, and 3 minutes after injection represent 1, 2, 3, respectively. Three minutes after injection (3), there is retention of some contrast material compatible with first-degree venous insufficiency.

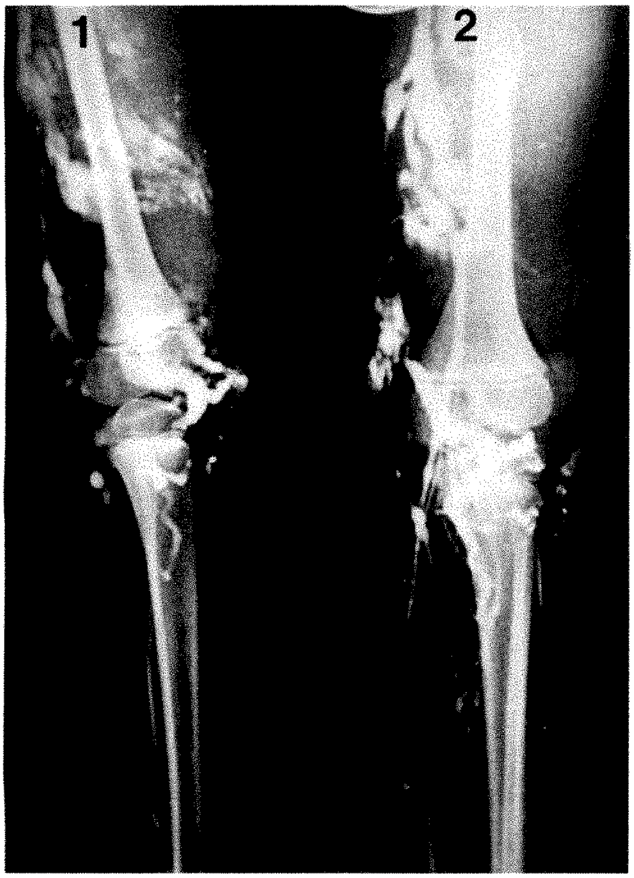

FIG. 1B. Superficial nonfunctional phlebography in the patient described in Figure 1A demonstrates spongy venous mass, a typical peripheral angiodysplastic lesion (2 projections).

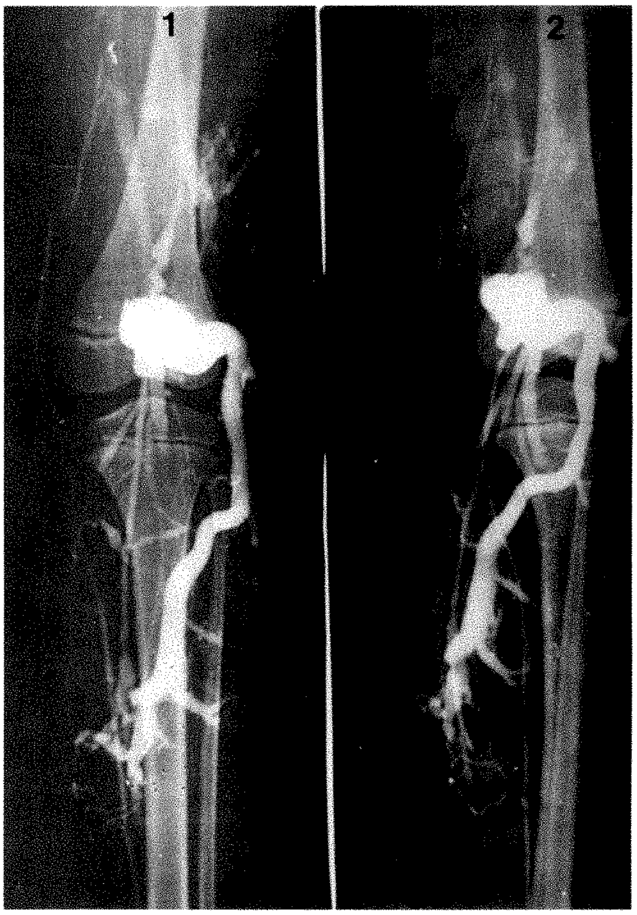

FIG. 2B. Superficial nonfunctional phlebography (in 2 projections) in the patient described in Figure 2A demonstrates peripheral angiodysplastic formation that resembles segment of persistent embryonal vein.

eurysms (4 patients), fusiform aneurysms (3 patients), and aplasia of the superficial femoral vein (3 patients) were the major abnormalities encountered. In this group, there was significant reflux from the deep venous system into the superficial venous malformations, mainly *via* atypical ultrashort communicating veins (Fig. 3). Venous insufficiency demonstrated in five patients of this group was more severe than that observed in patients in group A. There was no difference in the morphologic features and the extent of the angiodysplastic lesions in both groups. None of the patients had involvement of the greater or the lesser saphenous veins.[8]

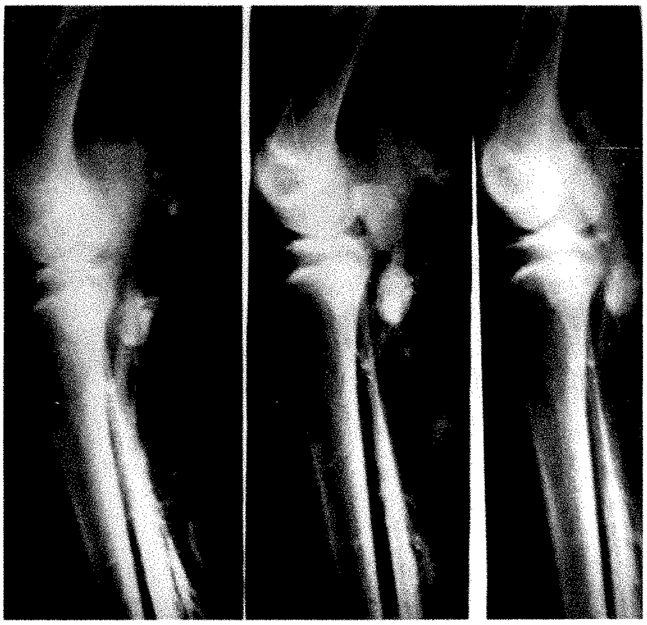

FIG. 3. Selective ascending functional phlebography in a 14-year-old boy demonstrates a rapid opacification of a peripheral angiodysplastic spongy malformation filled *via* multiple ultrashort invisible communicating veins. Three minutes after injection (3), there is still considerable retention of contrast material, third-degree venous insufficiency (the timing is identical to that of Fig. 1A).

Surgical Treatment

Eighteen patients underwent excision of the angiodysplastic lesions and ligation of the adjacent communicating veins (Table 4). Four of these patients required more than one session. The cosmetic and the functional results were very good in patients with mild and moderate forms of the disease. Patients with severe functional disability had temporary relief. The main clinical and venographic features of the different forms of SVS angiodysplasia and the results of treatment are summarized in Table 5.

Discussion

Congenital angiodysplasia is a well-recognized clinical entity. All the patients in the current series belonged to a more defined clinical and radiologic entity, namely venous angiodysplasia.[4–6] These malformations are structural anomalies with errors of vascular morphogenesis resulting in gradual venous dilatation and formation of collaterals or shunting vessels.[2]

Venous angiodysplasia may present either as venectasia or as spongy masses.[4–6,8] The venectasia may vary from dilatation of the skin capillaries (port wine stain) to formation of giant, valveless venous trunks resembling remnants of embryonic veins. The most common presentation of these lesions is a conglomeration of dilated tortuous venous trunks.

The spongy masses are actually smooth cavernous spaces lined with normal endothelium and surrounded by connective tissue and muscular elements similar to those observed in a normal vein. The cavernous spaces occasionally contain thrombi or calcified phleboliths.[5,6]

The extension of the venous lesions varies from an intracuticular or subcutaneous (superficial to the fascia

TABLE 5A. *Clinical Features of the Different Forms of Severity of SVS Angiodysplasia*

Severity	No. of Patients	Symptoms	Clinical Findings	Anatomic Level of the Angiodysplastic Lesions
Mild	11	Asymptomatic	Intracuticular lesions (port wine stain), subcutaneous varicosities	Intracuticular Subcutaneous
Moderate	8	Localized pain	Prominent varicosities, venous lump	Subcutaneous, subfascial
Severe	5	Disabling pain, swelling	Swollen extremity, painful venous lump, hemarthrosis, muscle atrophy	Subfascial

propria) location to subfascial involvement, *i.e.*, intermuscular, intramuscular, synovial with joint involvement, or intraosseous lesions.[4] Most of the patients have bi- or tri-level involvement.

The venous drainage of the normal lower extremity consists of three main systems: deep, superficial, and communicating veins network. This classification is frequently unsatisfactory in defining the abnormal location and extension of the congenital venous abnormalities. Therefore, we have simplified the classification of venous angiodysplasia and divided these lesions into two groups: (1) malformations of the deep venous trunks (DV), which are the major draining veins of the lower extremity; (2) malformations of the superficial veins (SVS), including all veins located superficially or deeper to the deep fascia. All the patients in the current series had malformations of the SVS. In addition, 10 had significant pathologic features of the deep venous system (DV). The existence of combined SVS and DV pathologic features has been described by several authors.[9–11] The presence of conglomerates of superficial varicose veins atypically located on the lateral aspect of the lower extremity is not diagnostic but suggestive of a possible involvement of the deep venous system. The use of selective ascending functional phlebography is mandatory for an anatomic and functional assessment of this complex abnormality.[8,12] Any attempt to ligate or excise the superficial varicose veins, which are the main alternative draining routes in this situation, will compromise the affected limb.[4,11–13]

The communicating venous system plays a major role in the clinical course and the final outcome of SVS angiodysplasia.[14] Venous reflux is encountered particularly in patients with atypical communicating veins. Three forms of atypical communication were previously described: (1) persistent long embryonic venous trunks, (2) single short communicants, and (3) numerous ultrashort communicants.[7] Single short communicants in six patients (Fig. 2A) and numerous ultrashort communicants in seven patients (Fig. 3), were the major routes of venous reflux from the deep venous system into the superficial angiodysplastic malformations. In our experience, meticulous ligation of the typical and atypical communicating veins improves the cosmetic results and the long-term outcome of the surgically treated patients. The ultrashort communicants preclude successful removal of angiodysplastic formations since they are too small and numerous to be occluded surgically.

Selective ascending functional phlebography is our preferred method to assess the degree of venous insufficiency in patients with congenital venous malformations.[7,12] The majority of the patients (19 patients) in the current series had a well compensated venous return (Fig. 1A). However, four patients with combined deep and superficial veins pathology had second- and third-degree venous insufficiency. One patient with normal

TABLE 5B. *Venographic Features of the Different Forms of Severity of SVS Angiodysplasia*

Venographic Findings				
Deep Veins	Reflux	Venous Insufficiency	Treatment	Results
Normal	Absent or mild	Absent	Observation or complete excision of lesion	Excellent
Normal or aneurysms	Via typical or atypical short communicants	Absent or first degree	Complete or partial excision with ligation of the incompetent communicating veins	Satisfactory or very good
Normal or aneurysms or aplasia	Via multiple ultrashort communicants	Second or third degree	Partial excision, supportive elastic bandage	Poor or Satisfactory

deep venous system had a second-degree venous insufficiency due to extensive SVS angiodysplasia involving the entire thigh muscles and the knee joint (Fig. 3).

The main clinical and venographic features of SVS angiodysplasia are summarized in Tables 5A and B. The classification of the patients into three groups according to the severity of the disease (mild, moderate, and severe) is helpful in planning the appropriate conservative or surgical treatment. It should be emphasized that the morphologic appearance of SVS angiodysplasia lesions is identical in the three forms of the disease. On the other hand, local swelling, pain, muscle atrophy, presence of deep angiodysplastic lesions, venous reflux *via* atypical communicants, and the presence of deep venous abnormalities with venous insufficiency have a poor prognosis.

We recommend that any therapeutic approach applied to this rare and complex entity should be based on the complete clinical, anatomic, and functional workup to prevent serious and even life-threatening complications.

Results of Surgical Correction of Anorectal Malformations

A 10–30 Year Follow-up

NAOMI IWAI, M.D., JUN YANAGIHARA, M.D., KAZUAKI TOKIWA, M.D., EIICHI DEGUCHI, M.D.,
and TOSHIO TAKAHASHI, M.D.

Of 119 patients with surgical correction of anorectal malformations, 47 who were 10–30 years of age were interviewed personally and had manometric studies to evaluate postoperative continence. This clinical study included not only long-term anorectal function but also sexual function. Patients with low type anomalies or with intermediate type anomalies were more likely to be continent, whereas patients with high type lesions had some problems with continence. However, only two of the 16 patients (12%) with high type anomalies were classified as having poor results. This rate is perhaps lower than might be expected. Thus, incontinent patients may become continent even if they were classified as having fecal incontinence before 6 years of age. Most patients who were 15–30 years of age had normal sexual function except for two females with irregular menstruation. These results indicate that achievement of fecal continence and sexual function in patients with high type anomalies treated by abdominoperineal rectoplasty depends on careful dissection as close as possible to the rectal wall and bringing the terminal bowel down exactly within the sling of the puborectal muscle.

From the Division of Surgery, Children's Research Hospital, and the First Department of Surgery, Kyoto Prefectural University of Medicine, Kyoto, Japan

THE MAIN OBJECT OF any surgery for anorectal malformations is to achieve anal continence. In addition to bowel function, sexual function is also important. However, very few reports[1,2] have mentioned sexual function after surgery for anorectal malformations.

This paper reports the long-term results with regard to bowel and sexual functions in patients treated surgically for anorectal malformations who are now 10–30 years of age.

Clinical Data

One hundred forty-one patients with anorectal malformations were treated at the Children's Research Hospital of Kyoto Prefectural University of Medicine from 1960 to 1986 (Table 1). Of these patients, 66 (51 males and 15 females) had high type anomalies, 24 (16 males and 8 females) had intermediate type anomalies, and 51 (34 males and 17 females) had low type anomalies.

A total of 121 surgical corrections were performed on 119 patients (Table 2). Two of the 121 patients had undergone cut-back anoplasty in the neonatal period and anal transplant at 2 or 3 years of age.

The usual operative procedure in this division has been colostomy for the high and intermediate types in the neonatal period, followed by abdominoperineal rectoplasty, in which the rectum was dissected carefully along the rectal wall to preserve the pelvic nerves. The sling of the puborectal muscle was well identified by causing contraction of the puborectal muscle with an electric stimulator, and the pelvic floor was pushed upward from the perineal side by the surgeon's left hand so that the sling of the puborectal muscle could be well visualized. The center of the external sphincter muscle was also identified by causing contraction of the muscle with the electric stimulator. Low type anomalies were treated by neonatal perineoplasty. Anal transplants were performed at 3 or 4 months of age after anal dilatation, or cut-back anoplasty was performed soon after birth, followed by an anal transplant at 2–3 years of age.

Postoperative complications (Table 3) were observed in 31 patients (26%). Prolapse of the rectal mucosa occurred in 14 patients, and the excess rectal mucosa required trimming in all 14 patients. Anal stricture was present in eight patients, leading to secondary megacolon in two patients. Three of the eight patients required

secondary anoplasty since anal dilatation was not effective. Intestinal obstruction due to adhesions was present in four patients after abdominoperineal rectoplasty, and all four patients recovered after surgical division of the adhesions. Bowel retraction after pull-through occurred in two patients and recurrent rectovaginal fistula occurred in one patient.

Type of Anomaly	No. of Cases	Age (Years)	(Mean ages)
High type	16	10–20	(12)
Intermediate type	13	10–24	(13)
Low type	18	10–30	(13)

Current Bowel Control

Forty-seven patients, 10–30 years of age, were interviewed personally and assessed clinically: 16 patients, 10–20 years of age, with high type anomalies, 13 patients, 10–24 years of age, with intermediate type anomalies, and 18 patients, 10–30 years of age, with low type anomalies (Table 4).

Function was evaluated by the Kelly score system[3] on the basis of three criteria: (1) control of feces and bowel habits, (2) fecal staining, and (3) sling action of the puborectal muscle. The results were classified as good (Kelly 5–6), fair (Kelly 3–4), and poor (Kelly 0–2).

The current bowel control of these patients is shown in Table 5 All 18 patients with low type anomalies had good control, and of the 13 patients with intermediate type anomalies, 10 (77%) achieved good control. On the other hand, only seven of the 16 patients with high type anomalies had good control, and two of them (12%) had poor control.

Manometric assessment was usually performed without anesthesia, except in restless children who required mild sedation. The probe was perfused with a constant infusion of 10 ml/h. Of the 47 patients assessed clinically, 41 had manometric studies to evaluate postoperative continence. The results are summarized in Table 6.

All of the 14 patients with low type anomalies had both a high pressure zone in the anal canal and an anorectal reflex. Of the 12 patients with intermediate type anomalies, 11 (92%) had a high pressure zone and six (50%) had an anorectal reflex. Of the 15 patients with high type anomalies, however, 11 (73%) had a high pressure zone and only three (20%) had an anorectal reflex.

Sexual Function (Tables 7 and 8)

Five male patients, 15–20 years of age, were interviewed regarding their sexual function: erection, ejaculation, and history of marriage. All five patients had normal erections and ejaculations. One patient was married and enjoyed normal sexual activities.

Seven female patients, 15–30 years of age, were interviewed regarding menstruation and history of marriage. Five of the seven had regular menstruation, and two had irregular menstrual periods; one had had a rectocloacal fistula and the other had a rectovaginal fistula. Three patients were married, and one had had a normal pregnancy and delivery.

TABLE 5. *Clinical Assessment and Type of Anorectal Malformation*

Type of Anomaly	No. of Cases	Clinical Assessment: Good	Fair	Poor
High	16	7 (44%)	7 (44%)	2 (12%)
Intermediate	13	10 (77%)	3 (23%)	0
Low	18	18 (100%)	0	0

TABLE 6. *Results of Anorectal Manometry*

Type of Anomaly	No. of Cases	Anorectal Manometry: Presence of HPZ	Presence of Anorectal Reflex
High	15	11 (73%)	3 (20%)
Intermediate	12	11 (92%)	6 (50%)
Low	14	14 (100%)	14 (100%)

HPZ = high pressure zone.

Discussion

Specific complications of surgery were observed in 31 of 119 (26%) patients who had had surgical treatment for anorectal malformations. This rate is somewhat lower than that in series of Hecker et al.[4] Anal strictures were especially less frequent, presumably because of careful anal dilatation begun 2 weeks after operation. On the contrary, the rate of mucosal prolapse in our series was 12%, which is almost three times that in the series of Hecker et al. The goal of a cosmetically satisfactory anal opening as well as one that functions normally depends primarily on the operative technique. Therefore, care should be taken to slide the perianal skin flap into the new anal canal so that mucosal prolapse is avoided.

In the current series poor results were not observed either in patients with intermediate type anomalies or in those with low type anomalies. However, two of the 16 patients (12%) with high type anomalies had poor results, and the remaining 88% had good or fair results. In our previous report,[5] 23% of those with high type anomalies had poor results, but the mean follow-up period was 5.75 years. Therefore, this repeat clinical assessment demonstrates that incontinent patients may become continent even if they had fecal incontinence before 6 years of age. Smith et al.[6] stressed the importance of parental assistance in training and of the patient's desire, cooperation, and mental ability. Intellectual development after six years of age through the experiences of school life is one of the steps towards the achievement of continence, in addition to physiotherapy.

We previously reported that continent patients characteristically had a very high pressure zone in the anal canal. Therefore, in view of the current manometric evidence, a high pressure zone and an anorectal reflex were considered to be chief parameters for objective assessment. A high pressure zone was present in 73% of the high type anomalies. This finding correlates well with the clinical evaluation, in which 88% of the patients with high type anomalies had good or fair results. On the other hand, only 20% of the patients with high type anomalies had an anorectal reflex. In our previous study, 20% of the patients with high type anomalies had an anorectal reflex. These results suggest that high pressure zones might be achieved in patients with good or fair results by contractions of the voluntary muscles as intellectual development progresses or as a result of physiotherapeutic training.

5	16	Low	Regular	Single
6	25	Low	Regular	Married (1 child)
7	30	Low	Regular	Married

Sexual dysfunction after major rectal surgery in adults is extremely common.[7,8] In the current study, however, most of the patients with anorectal malformations had normal sexual activity except for the two patients with irregular menstruation. Nixon and Puri also reported that all patients examined had normal sexual activity except for one patient with a permanent colostomy.[1] These results indicate that in the surgery of anorectal malformations, refinements of surgical technique, such as dissection as close as possible to the rectal wall, can prevent postoperative sexual disturbances. Therefore, the majority of patients with anorectal malformations can expect a good quality of sexual activity.

Varicocele in Youth

A Therapeutic Dilemma

JOEL SAYFAN, M.D.,* YIGAL SOFFER, M.D.,† HANNA MANOR, M.D.,‡ ELA WITZ, M.D.,‡ and RUBEN ORDA, M.D., M.S.*

The need for treatment of asymptomatic varicocele in youth is controversial. In the current study testicular volume and seminal variables were evaluated in three groups: young varicocele patients with undetermined fertility potential, infertile varicocele patients, and a control group of young males. The testicular volume was determined by ultrasonographic measurements. The results revealed a significant loss of "testicular mass" in both varicocele groups compared with the control group. The seminal findings disclosed a severe disturbance of spermatogenesis in the older varicocele group, whereas in the younger varicocele patients only the total spermatic count was significantly depressed. This difference in severity of functional impairment between the younger and older varicocele groups possibly points towards progressiveness of damage to the testicles. A more decisive therapeutic approach to the young male with asymptomatic varicocele and unknown fertility status could be justified.

From the Departments of Surgery "A", Obstetrics and Gynaecology,† and Diagnostic Radiology,‡ Assaf Harofeh Medical Center, Sackler Faculty of Medicine, Tel Aviv University, Zerifin, Israel*

VARICOCELE IS CONSIDERED by most authors as the most frequent treatable cause of male infertility,[1,2] although there are a few reports to the contrary.[3,4]

The impaired testicular function in the infertile male with varicocele is expressed by deranged seminal findings,[5] histologic changes,[6] and decreased testicular size.[1,7] Recent studies stress the prognostic value of testicular volume in patients who have surgical treatment of varicocele.[8] Testicular volume and tonometry (consistence) were positively correlated with semen quality.[9]

Due to the ample evidence connecting varicocele and infertility, most clinicians do not hesitate as to the active approach when confronted by a patient in this setting. However, controversy exists over the appropriate management of the very young male whose varicocele is an incidental finding and his fertility potential is still unknown.

Interestingly, idiopathic varicocele is a neglected entity in classic pediatric and pediatric–urology texts,[10] yet vast epidemiologic studies involving thousands of children and adolescents revealed that the incidence of varicocele is comparable to that of the adult male population.[10–13] An explanation for this lack of preoccupation by pediatric clinicians regarding this common condition (incidence of approximately 15% in large series), is that pediatricians usually perform examinations with the children lying down. Varicocele tends to disappear in the supine position and thus the genitalia are not examined thoroughly enough.

Several recent studies of children and adolescents with varicocele came up with findings that can be termed "alarming": a sharp decrease in size of the left testicle was noted in 74%, 77%, and 81% of these boys in three separate studies.[11,12,14] Furthermore, 90% of testicular biopsies performed in two series of prepubertal and pubertal boys revealed histologic findings consistent with disturbed spermatogenesis, similar to those described in infertile adults with varicocele.[12,15]

The current study was done to provide controlled data concerning the question whether or not the fertility potential is already endangered in the very young male with varicocele.

Materials and Methods

The testicular volume and seminal variables were tested and compared in three groups of patients: (1) "young varicocele" group—21 patients, age range 16–23 years, mean age 19 years. All had unilateral left varicocele diagnosed clinically, with unknown fertility

status, without previous significant urogenital diseases, trauma, or surgery in the genital area. Normal hormonal status was assumed by a well developed male habitus. (2) "varicocele infertility" group—18 patients, age range 25–38 years, mean age 30 years. These patients were referred from the Infertility Clinic after evaluation of sterile marriage. A left varicocele was the only pathologic finding in these otherwise healthy males. (3) control group—18 young males, age range 16–38 years, mean age 25 years. They were referred to surgery because of minor disorders completely unrelated to the urogenital system. No genital abnormalities were found on physical examination. They were randomly assigned for the study, and thus some of them fathered children, whereas in others the fertility potential was still unknown.

TABLE 1. *Testicular Volume Determinations*

	Mean Right Testicular Volume (ml)	Mean Left Testicular Volume (ml)	Difference Between Right and Left Mean Volumes (ml)
Young varicocele group	11.95	9.50	2.45 ($p < 0.001$)*
Varicocele infertility group	12.10	9.21	2.89 ($p < 0.001$)*
Control group	15.48	14.46	1.02 (not significant)

* Student's t-test.

Ultrasonographic Determination of Testicular Volume

The examinations were performed using the following equipment: real-time unit Dynex (Elscint, Haifa, Israel) with 5-MHz and high-resolution 10-MHz transducers; real-time unit Sonoline-8000 (Siemens, Erlangen, West Germany) with 7-MHz transducer; and a B-mode gray-scale ultrasound (Picker, Northford, USA) with a 5-MHz transducer.

Examinations were performed with the patient in the supine position on both sides by the "gloved hand" technique, obtained by direct contact of the transducer with the scrotal skin.[16] Sagittal and transverse scanning planes were used to measure the volume of each testis. Volume determinations were made using the formula for the volume of an ellipsoid:

$$0.523 \times \text{length} \times \text{width} \times \text{thickness}^{17} \quad \text{(Fig. 1)}$$

Seminal Parameters

In the "young varicocele" and "control" groups only one semen specimen was examined due to technical difficulties in obtaining multiple specimens in these patients. The abstinence period was at least 3 days. In the "varicocele infertility" group, multiple samples were available. The following variables were evaluated: (1) total sperm count; (2) motility index (% motility × grade); and (3) morphology (by the light microscopy score).

Statistical Analyses

The testicular volume values, seminal morphology, and motility index were analyzed using the Student's t-Test. The total sperm counts were evaluated by the Mann-Whitney nonparametric test because of unbalanced data.

Results

Testicular Volume

In each group the mean volume for left and right testicles and the difference between both were calculated. The volumes were strikingly similar in both varicocele groups (Rt—11.95 ml and 12.10 ml; Lf—9.50 ml and 9.21 ml), compared with the control group (Rt—15.48 ml, Lf—14.46 ml) (see Table 1).

Mean testicular mass, being the sum of right and left mean volumes, was calculated for each group. The values were statistically compared among the groups showing that the testicular mass in both varicocele groups was significantly smaller than in the control group, whereas there was no difference between the varicocele groups compared with each other (see Table 2).

Seminal Findings

The variables tested displayed no significant difference in motility index and morphology between the control and young varicocele groups; however, some difference showed when the total sperm counts were compared ($p < 0.01$).

When the control group was compared with the varicocele infertility group the difference was statistically significant in all variables evaluated. Some slight difference showed in the motility index only between the varicocele groups (see Tables 3 and 4).

TABLE 2. *Mean Testicular Mass*

Groups Compared	Mean Testicular Mass Values (ml)	Significance of Difference
Control *versus* young varicocele	29.94/21.45	$p < 0.001$*
Control *versus* varicocele infertility	29.94/21.31	$p < 0.001$*
Young varicocele *versus* varicocele infertility	21.45/21.31	Not significant

* Student's t-test.

TABLE 3. *Total Sperm Counts*

Group	Range	Mean
Control	26×10^6–418×10^6	186×10^6
Young varicocele	0.2×10^6–260×10^6	71×10^6
Varicocele infertility	0.2×10^6–139×10^6	35×10^6

Discussion

The age range in our groups of patients was between 16 and 38 years. We excluded younger children and older men (although we treated several varicocele patients 12–16 years of age), so as to include in the study only fully developed gonads (postpubertal) and before any functional decline could be attributed to advanced age.

Testicular volume is generally assessed by different kinds of orchiometers or calipers.[1,8,9,18] In these methods the size of the testicle is measured including the scrotal skin, testicular envelopes, and differing amount of fluid in the tunica vaginalis. In studies using ellipsoid rings being compared with the testis, the subjective impression of the examiner is an additional factor of inaccuracy. Our method of ultrasonographic determination of the volume measures accurately the testicular tissue mass only. This fact could account for the smaller values in our patients compared with figures in the literature (20–25 ml normal adult volume).[1,8,18]

The fact that in the control and the young varicocele groups, only one seminal sample was analyzed is a drawback. However, it is countered by the fact that we consider mean, collective data while comparing the groups. Thus, the individual fluctuations in seminal variables that could arise on repeated examinations should not significantly affect the general trend in any given group.

Our current data reveal that the left testicle is significantly smaller than the right in both the young varicocele and varicocele infertility groups, which is in sharp contrast to the control group. Moreover, the values of volumes of both testicles in the varicocele groups are strikingly similar, despite that in the young varicocele group the patients are significantly younger (mean age: 19 *vs.* 30 years in the infertile group) (Table 1). When we compare the testicular mass, there is a significant difference between the control group and the two varicocele groups, whereas no difference is found between both varicocele groups (Table 2).

It seems, therefore, that in the young males with varicocele and unknown fertility potential, there already exists a significant loss of testicular mass similar to older varicocele patients with known fertility problems.

When we consider the seminal findings (Tables 3 and 4), it is obvious that in the varicocele infertility group all variables are significantly depressed compared with the control group; most prominent are the disturbance in motility and total count, less in morphology. However, in the young varicocele group, the only significantly de-

TABLE 4. *Differences in Seminal Findings*

Groups Compared	Difference Among Groups: Motility Index	Difference Among Groups: Morphology	Difference Among Groups: Total Sperm Count
Control *versus* young varicocele	None	None	Significant ($p < 0.01$)†
Control *versus* varicocele infertility	Significant ($p < 0.001$)*	Significant ($p < 0.05$)*	Significant ($p < 0.002$)†
Young varicocele *versus* varicocele infertility	Significant ($p < 0.01$)*	None	None

* Student's t-test. † Mann-Whitney nonparametric test.

pressed variable is the total sperm count. Some slight disturbance can be detected in the motility index. All these findings suggest that a correlation exists between decrease in testicular mass and disturbed spermatogenesis. This is consistent with some previous observations; it was claimed that the "total testicular volume yields a reasonable estimate of the total quantity of testicular tissue available for spermatogenesis."[8] Another author reported that "mean testicular volume can be strongly correlated with sperm counts."[18]

Our data also suggest that the detrimental effect of varicocele on testicular function is progressive. The fact that in our study the seminal variables were more disturbed in the older varicocele group compared with the young varicocele patients, could support this assumption. Although Lipshultz and Corriere found progressiveness of testicular atrophy in varicocele patients,[7] in our current study the loss of testicular mass was already well established in the young varicocele group, being similar to that existing in the older patients.

In this context it should be noted that in the few studies of children with varicocele, left testicular hypotrophy was a constant finding, being most pronounced and prevalent in the prepubertal age group.[11,12,14] These authors suggest that testicular hypotrophy in varicocele is in fact testicular growth arrest caused by an unknown mechanism during the most critical period of testicular growth and development, the pubertal years. The findings of histologic changes consistent with disturbed spermatogenesis in young boys with varicocele should not be forgotten either.[12,15]

These considerations supported by our current data suggest that an active therapeutic approach to the young male with varicocele could be justified, even in asymptomatic patients with fertility potential still unknown.

There is ample evidence proving that the basic physiologic disturbance in varicocele is the reversal of flow in the venous drainage system of the testis, and thus the modern therapy of varicocele aims at abolishment of this reflux. The classic surgical procedure described in 1918 by Ivanissevitch and modified by Palomo,[19] consists of high ligation of the internal spermatic vein along its retroperitoneal course. Recently, a nonoperative method of percutaneous venographic embolization of the internal spermatic vein and its main collaterals has been introduced. However, we have shown previously that the internal spermatic vein incompetence is not the only source of reflux in some cases of varicocele. In a considerable percentage of patients, a hemodynamic derangement in the external (cremasteric) spermatic vein can be demonstrated as well.[20] In these "combined reflux" cases the classic operation of high ligation of the internal spermatic vein or percutaneous embolization could be inadequate and thus could account for the surgical and spermatologic failures.[21] Accordingly, we described a transinguinal operative approach permitting simultaneous ligation of the internal and external spermatic venous systems.[22] Currently, a prospective evaluation of these three methods of treatment (the classic high ligation operation, the transinguinal simultaneous ligation, and the embolization) is being conducted in our department.

The offensive factor causing the functional and histologic damage to the testes in the presence of varicocele has not been conclusively identified yet. Whether it is a derangement in temperature regulation or some "mysterious toxic" substance brought by the venous reflux, the fact is that an effective abolishment of this hemodynamic disorder ameliorates in a considerable percentage of patients the testicular function as reflected by spermatologic variables, and even augmentation of the testicular mass.[4,8,15,18]

There are two other pathologic conditions commonly affecting the male gonads in the pediatric age group: the undescendent testis and testicular torsion. In these disorders, even if a unilateral lesion is present and even if it is promptly treated surgically, the incidence of later infertility is significantly higher than in the general male population. Here, just as in varicocele, it is still unknown why a unilateral testicular pathology should affect the function of both testicles. It was already suggested that this detrimental sympathetic effect of the diseased testicle on the healthy one would be aborted by performing early orchiectomy instead of orchipexy in cases of cryptorchidism or torsion. Whether a similar suggestion could be made by analogy in varicocele is a hypothetical or perhaps a philosophical question at the current stage of the state of arts. It should not be ignored that here we have more conservative and effective modes of treatment, which is not the case in infertile males who had testicular torsion or undescendent testis in childhood. However, this question is challenging enough to be tested by an experimental study in laboratory animals.

If the detrimental effect of varicocele on testicular function may be progressive as also partially suggested by our seminal variables, a recommendation to undertake a more thorough active screening among schoolage boys could be worthwhile. Whether early identification and treatment of prominent varicoceles accompanied by hypotrophic left testicles could prevent irreversible testicular lesions would be determined by long-term prospective studies.

Acknowledgments

We thank Mr. Isaac Reichbard and Mrs. Lucy Keleman from the Ultrasound unit, Diagnostic Radiology Department, for their technical assistance.

Principles and Practice of Research: Strategies for Surgical Investigators. H. Troidl, W. O. Spitzer, B. McPeek, D. S. Mulder, M. F. McKneally. 380 pp. New York: Springer-Verlag. 1986. $58.00.

THIS BOOK IS UNUSUAL in that the topic of principles and practice of surgical research has not heretofore been analyzed in such a clear, concise manner. The five editors from Canada, the Federal Republic of Germany, and the United States have selected 50 international contributors, all of whom are well known for their educational or scientific accomplishments. The book is divided into six sections, the first of which is entitled "The Rationale of Surgical Research." This is primarily an historical accounting of surgical research and a philosophical discussion of the importance of basic science and clinical science research to a surgical training program. Sections II, III, and IV contain largely practical information and will be of greatest interest to most readers. In Section II entitled "Starting the Research Process" there are contributions on methods of literature review, computer technology, the development of research protocols, the organization of clinical trials, and ethical aspects of research. The chapters "Statistics Demystified" and "Endpoints for Clinical Studies" are especially well done. Section III addresses "Selected Strategies of Research" and is devoted to topics in both experimental animal and clinical experimentation, all of which are of high quality, especially the chapter on "Clinical Research" and "Multicentre Collaborative Clinical Trials." Section IV, "Reporting Your Work," deals with the proper methods of abstract writing, presentation of data, either verbally or in a poster format at national and international meetings, and the chairing of scientific sessions either at large meetings or at closed conferences.

Although most of these chapters are brief, each contains much valuable information. Section V, "International Perspectives on Surgical Research," has contributions by surgical investigators from several countries. The final chapter in this section, "Common Characteristics and Distinctive Diversity in Surgical Research: An International Analysis," is written jointly by the five editors and provides a clear comparative analysis of surgical training programs, expenditures in biomedical research, and research training opportunities for surgeons in nine countries: Canada, England, France, Germany, Japan, Spain, Sweden, Switzerland, and the United States. The final section is titled "Opportunities in Surgical Research." There is a very good chapter on "Future Horizons in Surgical Research" by Dr. Francis D. Moore. It was he who did so well in developing bridges between the laboratory and the bedside, and he eloquently encourages young surgical investigators to concentrate their efforts at this interface if they are to make significant contributions in clinical research.

This is an excellent book, especially for those in surgical residency training programs or for junior faculty members who are just beginning their lives as surgical investigators. The editors have admirably achieved their goal and are to be commended for handling so ably this critically important area of surgery.

SAMUEL A. WELLS, JR., M.D.
St. Louis, Missouri

Trachea and Lung Surgery in Childhood, Vol. 21 in the series Progress in Pediatric Surgery. P. Wurnig (Volume Editor). 147 pp. New York: Springer-Verlag. 1987. $75.50.

DESPITE SOME OBSCURITY in translation, the preface to *Trachea and Lung Surgery in Childhood* by Professor Wurnig of Vienna, the volume's chief editor, points out that improvements in respirator therapy and intensive care have led to more frequent observation of congenital and acquired tracheal and bronchial deformities. This book is Volume 21 of the series *Progress in Pediatric Surgery* published by Springer-Verlag and is not intended to be a textbook. It contains 13 contributions primarily on airway disease, and four on pulmonary topics—three of these addressed to sequestration and one to congenital cystic adenomatoid malformation.

A wide variety of airway problems are discussed. These include: subglottic stenosis: congenital and acquired; treatment by laser and by reconstructive surgery; laryngotracheal cleft; tracheal excision and reconstruction for tumor and stenosis; use of cardiopulmonary bypass; and tracheobronchial and pulmonary tumors. The contributors chiefly present their own experiences in each topic, with a lesser effort at comprehensive presentation of the subject. This has the advantage of specificity and concreteness but leaves a little to be desired for the reader not already versed in laryngotracheobronchial surgery. The papers (I will call them that rather than chapters) vary greatly both in quantity of material reviewed (some are single case reports) and breadth of discussion. A certain amount of repetition is inevitable but it is not of such amount that it is troublesome.

The deficits noted actually give a measure of the rarity of these lesions, the difficulty of their management, and the diffusion of experience in management. Thus, there is merit in presenting a small number of cases from the authors' experience, rather than diffuse generalizations that might seem to a general reader to be derived from a much larger experience.

The contributors are from Austria, Finland, Germany, The Netherlands, Norway, and Switzerland. The English is generally clear and easily readable. Some additional editing both with respect to phrasing, word selection, and spelling would have smoothed out the rough spots.

Pediatric airway surgery remains one of the more difficult areas of airway reconstruction, in part due to the small volume of patients treated and in part to the special problems presented by the juvenile airway. This volume is a useful contribution for the surgeon with special interest in the area. For the more general surgical reader, it may serve the educational service of leading him to further study and a cautionary purpose in respect to trying his hand. A broader overview of the field might have made these aspects even clearer.

HERMES C. GRILLO, M.D.
Boston, Massachusetts

Practical Noninvasive Vascular Diagnosis, 2nd Edition. Richard F. Kempczinski, James S. T. Yao. 555 pp. Chicago: Year Book Medical Publishers. 1987. $50.00.

TECHNOLOGICAL ADVANCES in the instruments used for the detection of vascular diseases rapidly render obsolete many devices in an already bewildering array of machines. Easily readable books such as this second edition are of particular value to those not expert in this field.

The book is attractive, with appropriate subdivisions, easy-to-read type, and clear illustrations. The text is divided into five sections: the laboratory, instrumentation, extremity arterial evaluation, cerebrovascular evaluation, and venous evaluation. The contributors to these topics are recognized people in the field, and the presentations have an authoritative tone. The subjects are well covered, and the chapter subdivisions are arranged logically, clearly marked, and presented in similar formats. Each chapter has an appropriate bibliography.

Several chapters will be especially useful to those who need the information the most: the person relatively new to the field, *i.e.*, the young physician or nurse/technologist. Information needed to organize and operate a vascular laboratory will be helpful to anyone entering the area. The recommendations and concepts discussed are timely and pertinent.

The expanded roles of advanced instruments are the main reasons for the second edition. These discussions are complete, especially where concerned with cerebrovascular disease; however, unfortunately there is a great deal of repetition. Even many of the illustrations, especially of wave forms, B-mode images, and spectra, are similar.

The sections dealing with venous disease should resolve some of the current controversies regarding what is actually needed. Modern methods, such as B-mode imaging of veins, are lucidly discussed, and general recommendations described, as well as specific instructions on how best to perform the tests.

This book will be a valuable edition to the library of anyone interested in vascular diseases. Its main target appears to be those who are not already expert, and as such, it is successful in its aim.

MALCOLM O. PERRY, M.D.
Nashville, Tennessee

Clinical Surgery, Volumes 1 and 2. John H. David, William R. Drucker, Roger S. Foster, Jr., Richard L. Gamelli, Donald S. Gann, Basil A. Pruitt, Jr., George F. Sheldon. 3264 pp. St. Louis: The C. V. Mosby Co. 1987. $105.00.

WITH SO MANY EXCELLENT TEXTBOOKS on surgery currently available, why yet another? This question was asked by this reviewer, and by Doctor Davis in his introduction to this two-volume opus. The answer the authors provide is that a survey of undergraduate and postgraduate students and practicing surgeons demonstrated a need for a surgical textbook that took an innovative problem-solving approach.

The seven prominent editors have collected contributions from 101 noted American surgeons and have added their own. The format of *Clinical Surgery* is both different and unique. To accomplish this, these volumes have been divided into seven distinct sections, each addressing a specific component of surgical practice. In Part One, the reader immediately realizes that this is not a run-of-the-mill contribution when he/she discovers chapters on education and certification requirements in the United States today and another on the clinician's role in the cost of health care. The 11 chapters in Part Two comprise a miniphysiology textbook. Part Three is unique in that single problems are addressed; *e.g.*, abdominal pain, weight change, and alterations in blood pressure, to mention but a few. The ensuing sections deal with patient management and diseases of organs and systems. In each of these sections, as in most others, each chapter concludes with a concise summary of all the problems discussed, enabling an excellent rapid review. Emphasizing that trauma is the neglected disease of modern society, a comprehensive section on trauma follows, covering commonly (automobile) and uncommonly (elephants!) encountered injuries. A section on special areas (sepsis, transplantation, plastic and pediatric surgery) complete Volume Two.

Clinical Surgery is a masterful contribution. It will be well received by all students of surgery and will, I believe, establish the format of surgical and medical textbooks of the future.

JON A. VAN HEERDEN, M.B.
Rochester, Minnesota

The Psychological Experience of Surgery in the series **In General and Clinical Psychiatry.** Richard S. Blacher. 236 pp. New York: John Wiley & Sons. 1987. $31.50.

IN THIS SLIM VOLUME, Blacher and 11 contributors, liaison psychiatrists for surgical services, present the patient's view of the surgical experience. The stated goal is to share the patient's perspective with surgeons, surgical nursing staff, and other members of the surgical team. The unstated goal is to improve patient care as well as surgical outcome by improving communication between surgeons and their patients.

Keeping the traditional roles of the surgeon and psychiatrist intact, the psychiatrists share their intimate view of day-to-day patient interactions, allowing the surgeon to witness common fears, expectations, and misconceptions. Armed with this additional insight, the surgeon is thus able to recognize subtle signs of depression or irrational fears. The surgeon may then choose to deal with the problem directly or to consult a psychiatric colleague. This early intervention may circumvent the need for psychopharmacologic drugs and prevent progression to a major problem. A strength of this book is the focus on improving the quality of the seemingly inconsequential but powerful interactions between surgeons and their patients, such as explanation of the risks before obtaining informed consent for a procedure. There is no preaching about cold-hearted surgeons; rather the role of a self-assured surgeon to allay the anxieties and fears of the patient is underscored.

This 13-chapter volume would be improved by judicious editing. Although the chapters ostensibly focus on a specific aspect of surgery, such as bypass surgery for superobesity or lower limb amputation, important information relevant to *all* types of surgery is found in each chapter. It is worth the extra time to read through the book to find all the useful bits of information, regardless of whether the topic is of specific interest to the reader. For instance, the chapter on gynecological surgery contains a lucid discussion of the emotional impact of surgery involving sexual/reproductive organs and the attendant difficulties for a patient in discussing their concerns. The three chapters by Dr. Blacher are largely redundant. Although the material presented contains helpful suggestions for improved communication with and care of surgical patients, it is not apparent to this reader whether the repetition increased retention. The chapters on brain surgery, denial in cancer surgery and burn victims are not written with the surgeon-reader in mind; rather they are addressed to fellow liaison psychiatrists and do not fit conceptually with the rest of the material.

A final comment is that some of the clinical material emphasizes the dramatic rather than the commonplace, contradicting the authors' stated goal. This is particularly noticeable in the chapter on renal disease and transplantation. It contains a sensitive, thoughtful treatment of chronic illness and of the psychological aspects of receiving a donated organ and then describes a case wherein a 10-year-old boy commits suicide after learning that his estranged father donated his transplanted kidney.

RANDY L. GELLMAN, M.D.
New Haven, Connecticut

Cancer in the Neck: Evaluation and Treatment. David L. Larson, Alando J. Ballantyne, Oscar M. Guillamondegui. 280 pp. New York: Macmillan Publishing Co. 1986. $68.00.

THIS MULTIAUTHORED BOOK (44 authors) is edited by three head and neck surgeons from MD Anderson Hospital and Tumor Institute in Houston.

The six sections of the book are divided into two categories; they are devoted to basic immunobiological and clinical research. The original and innovative concepts of tumor immunobiology have been previously published and promulgated by Garth L. Nicholson, Professor and Chief of Tumor Biology at the MD Anderson Tumor Institute. These forward-thinking projections concerning the mechanisms of metastasis are worth the modest price of the book. The remaining sections on evaluation of neck specimens, radiotherapeutic considerations, neck dissection alternatives, chemotherapeutic considerations, and management of neck melanoma and unusual tumors of the neck are a conglomerate of confusing, unhelpful controversies based on personal biases.

The rationale for some approaches to therapy advocated by some of the authors lack reason and are based on false logic. This book fulfills all expectations of weakness anticipated in an uncoordinated, multiauthored text presenting retrospective studies of limited value.

Perhaps the most unredeeming tragedy is that a recognized, skilled group of surgeons at the MD Anderson Medical Center failed to communicate and develop what could have been one of the world's most outstanding prospective studies with a little cooperation.

One interesting and redeeming feature in this book is the thoughtful editorial comments that initiate each chapter.

This book will have limited influence on the practicing head and neck surgeon and can only confuse the novice resident. I recommend checking it out of the library for reference and for its extensive bibliography.

PAUL H. WARD, M.D., F.A.C.S
Los Angeles, California

THE PATHWAY
TO RAPID ACID SUPPRESSION

100 ml
Zantac® Injection Premixed
(ranitidine hydrochloride)
50 mg
98-1932-2/R-2 592802
Manufactured for Glaxo Inc.,
Research Triangle Park, NC 27709
by Abbott Laboratories, North Chicago, IL

Convenient

☐ Ready to use—no mixing needed

☐ Premixed 100 ml bag containing 50 mg ranitidine (as the hydrochloride)

☐ No need to refrigerate

☐ Stores for 12 to 18 months

Cost-effective

☐ Saves pharmacy and nursing time

Raises gastric pH in critical care patients for up to 8 hours*

No significant drug interactions with the hepatic P-450 enzyme system at recommended doses

☐ No clinically significant drug interactions between ranitidine and theophylline, phenytoin, or warfarin

Zantac®
Injection
Premixed
ranitidine HCl/Glaxo

Premixed 100 ml bag containing 50 mg ranitidine HCl

*Some patients may require q6h dosing.
See next page for brief summary of Product Information.

Glaxo/ROCHE

ZANTAC® Injection **BRIEF SUMMARY**
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Carcinogenesis, Mutagenesis, Impairment of Fertility: There was no indication of tumorigenic or carcinogenic effects in lifespan studies in mice and rats at oral doses up to 2,000 mg/kg/day.

Ranitidine was not mutagenic in standard bacterial tests *(Salmonella, E coli)* for mutagenicity at concentrations up to the maximum recommended for these assays.

In a dominant lethal assay, a single oral dose of 1,000 mg/kg to male rats was without effect on the outcome of two matings per week for the next nine weeks.
Pregnancy: *Teratogenic Effects: Pregnancy Category B:* Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
Use in Elderly Patients: Ulcer healing rates in elderly patients (65 to 82 years of age) treated with oral ZANTAC were no different from those in younger age groups. The incidence rates for adverse events and laboratory abnormalities were also not different from those seen in other age groups.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC®.

The following have been reported as events in clinical trials or in the routine management of patients treated with oral ZANTAC. The relationship to ZANTAC therapy has been unclear in many cases. Headache, sometimes severe, seems to be related to ZANTAC administration.
Central Nervous System: Rarely, malaise, dizziness, somnolence, insomnia, and vertigo. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.
Cardiovascular: Rare reports of tachycardia, bradycardia, and premature ventricular beats.
Gastrointestinal: Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain.
Hepatic: In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid IV for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.
Musculoskeletal: Rare reports of arthralgias.
Hematologic: Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.
Endocrine: Controlled studies in animals and man have shown no stimulation of any pituitary hormone by ZANTAC and no antiandrogenic activity, and cimetidine-induced gynecomastia and impotence in hypersecretory patients have resolved when ZANTAC has been substituted. However, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.
Integumentary: Rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia.
Other: Rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
NDC 0173-0362-38 2-ml single-dose vials (Tray of 10)
NDC 0173-0363-39 10-ml multi-dose vials (Singles)
NDC 0173-0362-01 2-ml single-dose, prefilled, disposable cartridge-needle units (Tray of 10)
NDC 0173-0362-00 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC® Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

Deadline: Copy received by the 15th of month will run in the second following month's issue, e.g. November 15th for January issue. Ads received after the 15th will run in the next available issue.

ALL SURGICAL SPECIALTIES, NATIONWIDE. Excellent Quality Of Life And Compensation. **Dr. Len Goodman, SMA, P.O. Box 25786, Charlotte, NC 28229. 704-536-2527.**

Associate Director for fully accredited university affiliated general surgery residency program in 900 bed tertiary care teaching hospital in southeastern U.S. Evolving trauma center, approved medicine, radiology and transitional residency programs, affiliated ENT, neurosurgery, ophthalmology, plastic surgery, and urology residencies. Must have strong academic background, demonstrated interest and experience in clinical research, resident and student teaching. Interest in trauma highly desirable. Must be board certified, minimum of 4 years experience. Limited practice opportunity. Academic appointment at university available. Salary and benefits negotiable. Reply to **Box ANN2D, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

ASST/ASSOC PROFESSOR & CHIEF OF ONCOLOGIC SURGERY, Department Of Surgery, Yale University School Of Medicine: The section of General Surgery is seeking a board certified M.D. in Surgery with specific training in surgical oncology; also must have established basic science research program and experience with clinical research protocols. Send vita and references to: **C. Elton Cahow, M.D., Vice-Chairman, Dept. of Surgery, Yale University School of Medicine, P.O. Box 3333, New Haven, CT 06510, by April 1, 1988.** All women and minorities are encouraged to apply. Yale is an equal opportunity/affirmative action employer.

BC/BE General Surgeon to associate with two active internists in NE Wisconsin. New clinic and modern hospital with state of the art ICU. **Box ANN2A, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19106.**

BC/BE GENERAL SURGEON to join busy private general/vascular practice in coastal New England town. On call every 6th day/wkend. Must have proven ability to get along with patients and peers. Vascular or thoracic experience helpful. **Box ANN2B, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

BOULDER, COLORADO: Thirty-five physician multispecialty group seeking Board Eligible/Board Certified General Surgeon with interest in Thoracic/Vasculas surgery. Interested please send CV to **John Day, M.D., Boulder Medical Center, P.C., 2750 Broadway, Boulder, CO 80302.**

CHAIRPERSON DEPARTMENT OF SURGERY Santa Clara Valley Medical Center, a 617-bed teaching hospital affiliated with Stanford University School of Medicine, invites applications for this important position. Must be board certified (preferably in General Surgery), possess administrative skills and experience, and be recognized as an outstanding clinician and teacher. Will be responsible for departmental administration, teaching and clinical practice including program development and resident, medical student, and allied health professional education. Surgical house staff and medical students come from Stanford University Hospital and School of Medicine and a close working relationship with the Department of Surgery at Stanford is required. SCVMC provides a full range of tertiary services, including spinal cord injury, burn, NICU, and Trauma care as well as a full range of surgical and medical sub-specialties. Please send CV to **Phillip Benaron, M.D., Medical Director, SCVMC, 751 South Bascom Avenue, San Jose, CA 95128.** SCVMC provides competitive compensation and benefits and is an equal opportunity employer.

CHIEF OF SURGERY: The Faulkner Hospital, Boston, Mass., an integrated program affiliate of New England Deaconess Hospital-Harvard Surgical Service and Tufts University School of Medicine, is inviting applications for chief of surgery. Qualifications: Board certified in general surgery; commitment to excellence in clinical service and teaching; demonstrated leadership skills and administrative ability. Address inquiries with CV to **John V. Woodard, Chairman, Surgical Search Committee, Faulkner Hospital, 1153 Centre Street, Boston, MA 02130.** Faulkner Hospital is an Equal Opportunity Employer.

GENERAL SURGEON—(BC/BE) to join busy 35 physician multispecialty group in Northeastern Massachusetts 35 miles from Boston. Excellent first year salary guaranteed with eventual association. Please send C.V. and references to **Leonard Block, M.D., Medical Associates, 199 Chelmsford Street, Chelmsford, MA 01824 - (617) 256-6511.**

GENERAL SURGEONS—Newly established prepaid group practice desires to begin offering general surgery services. Looking for general surgeons interested in establishing and building a department. Physicians must be from high quality residency programs. Positions available immediately. C.V.s to: **Larry A. Oates, M.D., Regional Medical Director, Carolina Permanente Medical Group, P.A. 2900 Highwoods Blvd., Raleigh, N.C. 27604 (919) 878-9870.**

Roswell Park Memorial Institute is recruiting a Cancer Research Clinician. The individual should be trained in GI Surgery with an emphasis on cancer and who has achieved some research distinction in his or her career. The service will be a merger of our Upper Gastrointestinal Service and our Colorectal Service. Included will be the Endoscopy Service. The successful candidate will be expected to take an active clinical part in some aspect of GI cancer, but mainly will be expected to have some academic scientific interest which can be pursued to develop scientific inquiry within this department and collaboration with our other basic scientific colleagues for a more organized approach to problems of gastrointestinal tract malignancy. There will be five to six attendings in addition to four or five fellows on this service. Interested candidates please submit curriculum vitae/resumes to: **Dr. E. Douglas Holyoke, Chief, Department of Surgical Oncology. Roswell Park Memorial Institute, 666 Elm Street, Buffalo, NY 14263.** Roswell Park Memorial Institute is an Equal Opportunity Employer.

Thoracic Surgeon experienced in adult cardiac, general thoracic and peripheral vascular surgery is needed to join 195 physician multispecialty prepaid group in Hawaii. Board certified associate. Excellent fringe benefits. Malpractice paid. Please direct curriculum vitae: **Hawaii Permanente Medical Group, Inc., 3288 Moanalua Road, Honolulu, HI 96819.** (AN EQUAL OPPORTUNITY EMPLOYER)

WANTED: General/peripheral vascular surgeon to join well-established general surgery group in scenic Northwest community of 50,000. Drawing are of 200,000. Hospital facilities include up-to-date surgical suite, ICU/CCU, out-patient facilities, vascular lab and complete state of the art X-ray facilities. To apply send C/V or reply **Box ANN2C, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

CASE # 24 **AGE:** 55 **SEX:** FEMALE

DIAGNOSIS: CECAL CARCINOMA

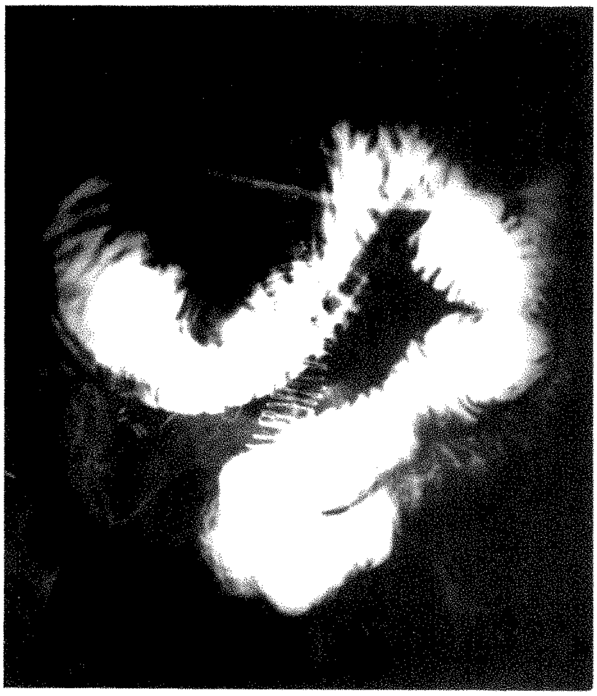
SYMPTOMS: ANEMIA (Hg 6 gm/dl)

OPERATION: RIGHT HEMICOLECTOMY & GASTROSTOMY

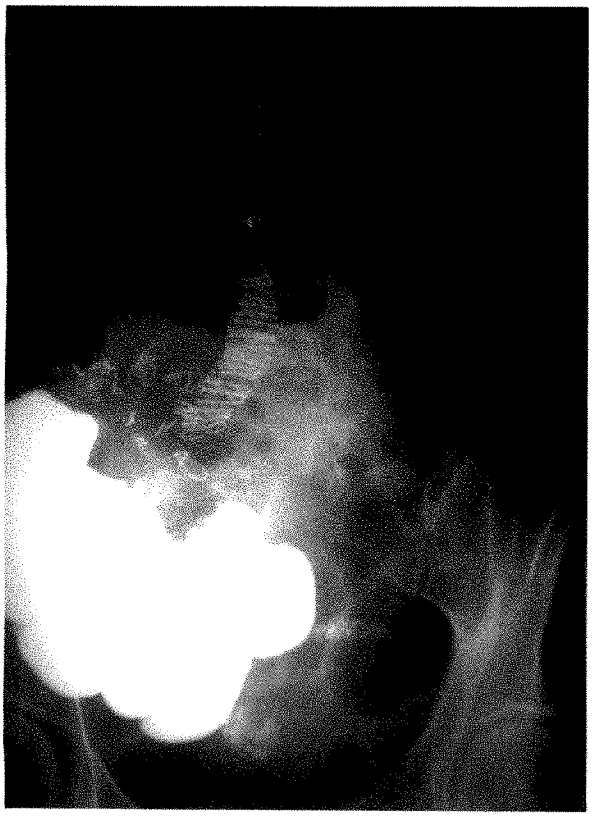
The patient had a right hemicolectomy with stapled (U.S. Surgical Corp) anastomosis and fascia closure and a MOSS® gastrostomy tube. The stomach and proximal duodenum were aspirated, with immediate simultaneous feeding into the distal duodenum.

Barium feeding 5 hours postop documented adequate motility. The deliberate excess was totally removed. No contrast (i.e.: excess feeding) escaped efficient aspiration within the proximal duodenum, to reflux into the stomach. (Figure A) Serial motility study showed barium had traversed the anastomosis and colon, and already was exiting in a spontaneous bowel movement by 21 hours postop. (Figure C)

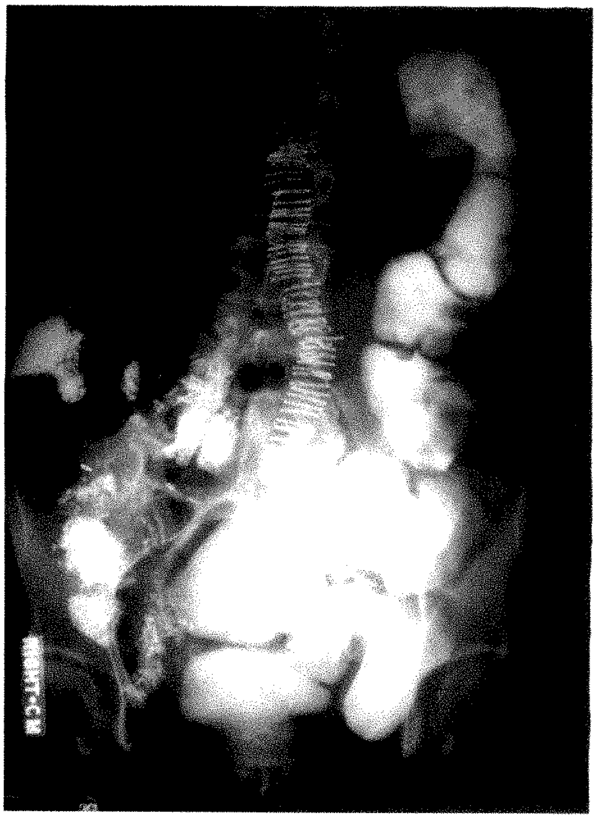
She received 300 ml/hr of Vivonex TEN (Norwich Eaton Pharm), absorbed 5,000 kcal the initial 20 hours, and then tolerated a general diet. She was the 4th patient discharged uneventfully 24 hours after bowel resection and reanastomosis.



A. Study @ 5 minutes (5 hours postop).
Note efficient removal of all excess barium, with none reaching the stomach.



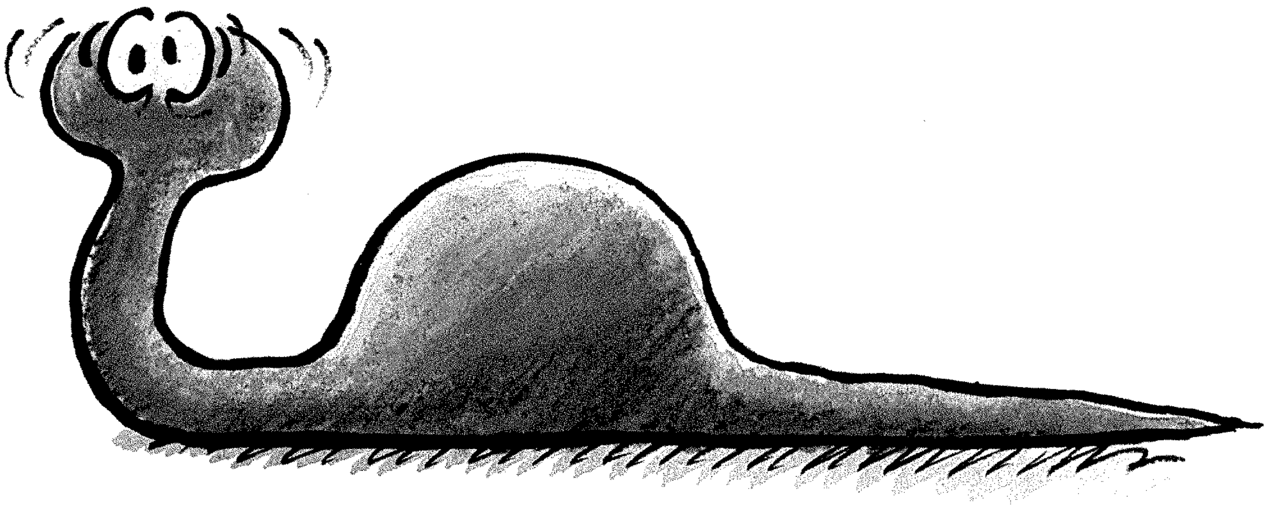
B. Motility @ 4 hours (9 hours postop).
All barium is within the ileum.



C. Motility @ 16 hours (21 hours postop).
Barium is exiting in a spontaneous bowel movement.

Call MOSS TUBES, INC (518) 674-3109 for introductory sample and literature.

If the movement needs improvement...
Colace® or Peri-Colace®



Recommend the time-tested anticonstipants that relieve gently and reliably. Colace (docusate sodium) softens the stool and helps prevent straining...especially important for patients with anorectal disorders.

When laxative action is also needed, Peri-Colace (casanthranol and docusate sodium) both softens stools and stimulates peristalsis to correct constipation, usually overnight.

Colace and Peri-Colace offer you the flexibility of 50 mg and 100 mg capsules, syrup, or liquid. Recommend them with confidence for virtually all your adult and pediatric patients.

Gentle relief you've relied on for over 25 years

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV
(cefotetan disodium)

Does so much for so much less than cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

† Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

CEFOTAN® (cefotetan disodium)

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

Totally current data and opinion on surgical management of colorectal cancers

Three volumes in the respected *Problems in General Surgery* series bring you up-to-the minute information that you can use *today* in your practice. Articles with real clinical relevance. Succinct presentations of major differences of opinion. Starkly different points of view on diagnosis and treatment—the questions you face when you make life-and-death decisions. The best thinking of leading practitioners to help you make the choices of modality of treatment most appropriate for each patient.

Here are information and insights that will challenge you to do something different and better in your practice the day after finishing each volume.

Abundant illustrations, diagrams, tables, charts. Totally current references, with commentary. *Each volume $30.00. Annual subscription (4 volumes) $59.00 (U.S.), $68.00 (elsewhere).*

Send for the volumes you need today. And begin your subscription to this challenging series with the next volume.

Explore the state of the art of TRAUMA SURGERY

NEW!

Edited by **Joseph A. Moylan, M.D.**

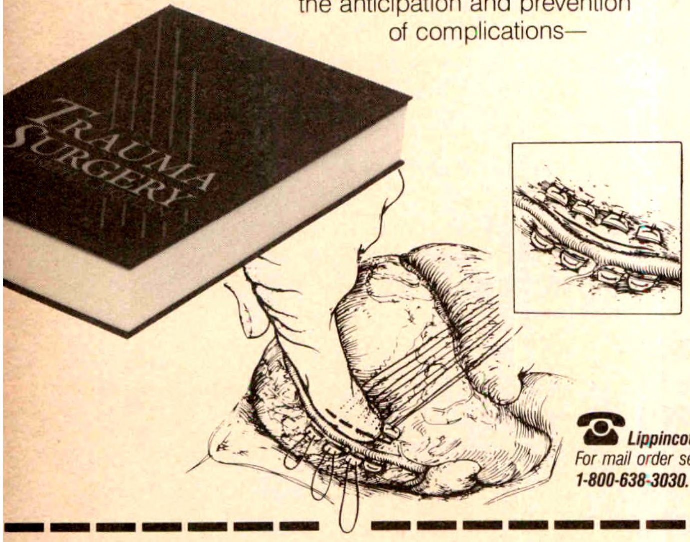
With 30 Distinguished Contributors

Brings you the state of the art of trauma surgery

This comprehensive reference focuses on modern-day surgical management of single- and multi-system trauma in the environment of sophisticated high technology used in diagnosis and treatment. It brings you the state of the art of trauma surgery as well as practical approaches used in daily practice by surgeons recognized for their trauma expertise.

Provides you with practical approaches to the complete care of the trauma patient

TRAUMA SURGERY addresses the *complete care* of the trauma patient. Integrating basic pathophysiology with practical technical information on assessment, evaluation, diagnosis, current surgical techniques, and the anticipation and prevention of complications—information addressing the *total management* of the trauma patient. Each chapter presents practical information on mechanism of injury, diagnostics, and therapeutic approaches, emphasizing practical, step-by-step methods which the contributing authors find helpful in solving and treating the trauma patient. Special sections cover shock, monitoring, management of a trauma unit, and immediate care of the trauma patient.



covers both common and complex injuries

Organized by area and type of trauma, the book covers practical approaches to the management of both common and complex injuries including: central nervous system trauma, facial trauma, neck injuries, thoracic trauma, burns, abdominal and pelvic trauma, vascular and nerve injuries, GYN trauma, and pediatric trauma surgery.

Emphasizes decision making

This remarkable book emphasizes decision making in trauma surgery. Alternative procedures and courses of action are outlined, however, specific recommendations are made.

579 Pages. 306 Illustrations. 55 Tables. 1988. $79.50.

THROMBOSTAT IS OPERATING UNDER A NEW COVER

New sterile packaging for 5,000- and 10,000-unit vials

THROMBOSTAT® (Thrombin, USP), along with a matched volume of diluent, is now available in a new sterile package–minimizing the potential for contamination. This new packaging permits the entire contents of the inner tray to be directly introduced into the sterile operating field.

Offers mixing convenience

Sterile packages of THROMBOSTAT also feature a convenient new transfer device. So mixing is faster and easier than ever before. With THROMBOSTAT, surgical preparation has never been simpler.

THROMBOSTAT®
THROMBIN, USP.

Please see next page for brief summary of prescribing information.

© 1987 Warner-Lambert Company

PD-34-JA-3853-P-1(1-87)

ROMBOSTAT® THROMBIN, USP
ovine Origin)

efore prescribing, please see full prescribing information. A Brief ummary follows:

rombostat must not be injected! Apply on the surface of bleeding ssue as a solution or powder.

DICATIONS AND USAGE
rombostat (Thrombin, USP) is indicated as an aid in hemostasis wher-ver oozing blood from capillaries and small venules is accessible.
In various types of surgery, solutions of Thrombostat may be used in njunction with Absorbable Gelatin Sponge, USP for hemostasis.

ONTRAINDICATIONS
rombostat is contraindicated in persons known to be sensitive to any of components and/or to material of bovine origin.

ARNING
ecause of its action in the clotting mechanism, Thrombostat must t be injected or otherwise allowed to enter large blood vessels. tensive intravascular clotting and even death may result. Throm-ostat is an antigenic substance and has caused sensitivity and lergic reactions when injected into animals.

ECAUTIONS
eneral:
nsult the absorbable gelatin sponge product labeling for complete formation for use prior to utilizing the thrombin-saturated sponge ocedure.

egnancy—
ratogenic effects: Pregnancy Category C. Animal reproduction studies ve not been conducted with Thrombin, Topical (Bovine). It is also not own whether Thrombin, Topical (Bovine) can cause fetal harm when ministered to a pregnant woman or can affect reproduction capacity. rombin, Topical (Bovine) should be given to a pregnant woman only if early indicated.

diatric Use:
fety and effectiveness in children have not been established.

DVERSE REACTIONS
lergic reactions may be encountered in persons known to be sensitive to vine materials.

OSAGE AND ADMINISTRATION
eneral: Solutions of Thrombostat may be prepared in sterile distilled ater or isotonic saline. The intended use determines the strength of the lution to prepare. For general use in plastic surgery, dental extractions, in grafting, neurosurgery, etc., solutions containing approximately 100 its per mL are frequently used. For this, 10 mL of diluent added to the 00 unit package is suitable. Where bleeding is profuse, as from cut rfaces of liver and spleen, concentrations as high as 1000 to 2000 units r mL may be required. For this the 5000 unit vial dissolved in 5 mL or 2.5 L, respectively, of the diluent supplied in the package is convenient. termediate strengths to suit the needs of the case may be prepared by lecting the proper strength package and dissolving the contents in an propriate voulme of diluent. In many situations, it may be advanta-eous to use Thrombostat in dry form on oozing surfaces.

ution: Solutions should be used immediately upon reconstitution. If cessary, refrigerate the solution and use within 3 hours of reconstitution.

e following techniques are suggested for the topical application of rombostat.
The recipient surface should be sponged (not wiped) free of blood fore Thrombostat is applied.
A spray may be used or the surface may be flooded using a sterile ringe and small gauge needle. The most effective hemostasis results hen the Thrombostat mixes freely with the blood as soon as it reaches the rface.
In instances where Thrombostat in dry form is needed, the vial is opened removing the metal ring by flipping up the plastic cap and tearing unterclockwise. The rubber-diaphragm cap may be easily removed d the dried Thrombostat is then broken up into a powder by means of a rile glass rod or other suitable sterile instrument.
Sponging of treated surfaces should be avoided in order that the clot main securely in place.

rombostat may be used in conjunction with Absorbable Gelatin Sponge. P as follows:
Prepare Thrombostat solution of the desired strength.
Immerse sponge strips of the desired size in the Thrombostat solution.
ead the sponge strips vigorously with moistened gloved fingers to move trapped air, thereby facilitating saturation of the sponge.
Apply saturated sponge to bleeding area. Hold in place for 10 to 15 conds with a pledget of cotton or a small gauze sponge.

erile Packages
rombostat Sterile Packages are available in two strengths, 5000 units d 10,000 units. A Sterile Package contains one sterile vial of Thrombostat, e sterile vial of Isotonic Saline Diluent, and one sterile transfer device. e Sterile Package may be used as follows:
Remove the Tyvek® blister lid by pulling up at the indicated corner. The rile inner tray can be lifted out or introduced into the operating field.
The cover to the sterile inner tray is removed by pulling up on the finger b, exposing the sterile contents.
Thrombostat solution of the desired strength is prepared using the nsfer device.
Alternatively, when Thrombostat in dry form is needed, the vial is ened as described above and the dried Thrombostat broken up into a wder by means of a sterile glass rod or other suitable sterile instrument.

rombostat Kit
rombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one rile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. e kit may be used as follows:
Remove the Tyvek® blister lid by pulling up at the indicated corner. The rile inner tray can be lifted out or introduced into the operating field.
The cover to the sterile inner tray is removed by pulling up on the finger b, exposing the sterile contents.
Thrombostat solution of the desired strength is prepared and the pump rayer cap inserted and seated on the Thrombostat solution vial. Note: veral strokes of the pump sprayer will be required before the Thrombos-t solution is expelled.
Alternatively, when Thrombostat in dry form is needed, the vial is ened as described above and the dried Thrombostat broken up into a wder by means of a sterile glass rod or other suitable sterile instrument.

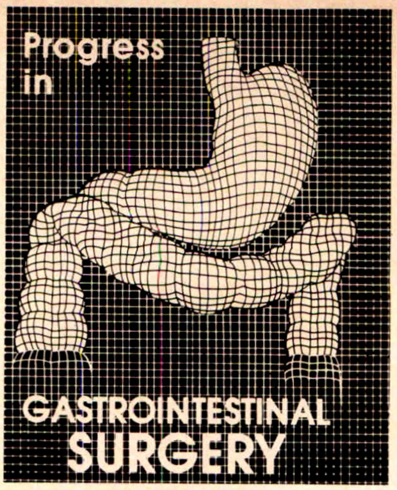
52nd ANNUAL COURSE



June 15-18, 1988

DEPARTMENT OF SURGERY, UNIVERSITY OF MINNESOTA

Progress in Gastrointestinal Surgery is the topic of the 52nd Annual Surgery Course to be presented by the Department of Surgery of the University of Minnesota Medical School, June 15-18, 1988 in Minneapolis.

FACULTY

Guest speakers will include Doctors Arthur H. Aufses, Jr., Scott J. Boley, H. Worth Boyce, Jr., Haile DeBas, Tom R. DeMeester, Arthur J. Donovan, F. Henry Ellis, Jr., E. Christopher Ellison, Victor W. Fazio, Josef E. Fischer, David Johnston, Keith A. Kelly, Edward E. Mason, Ronald L. Nichols, Mark B. Orringer, Hiram C. Polk, Jr., Mark M. Ravitch, William H. ReMine, Wallace P. Ritchie, Jr., David Sachar, William Silen, Richard Simmons, David B. Skinner, Howard M. Spiro, and Edward R. Woodward.

Host faculty will include the teaching staff of the University of Minnesota Medical School.

COURSE FEATURES

Didactic lectures, moderated panel discussion, audience participation panels, films, abstract booklet, printed proceedings, displays, continental breakfasts, lunches, refreshment breaks, reception, and one dinner. A spouse program and optional evening social events are also offered.

COURSE FEES

Regular fee: $425
Physicians in residency training programs: $200

DIRECT INQUIRIES TO:

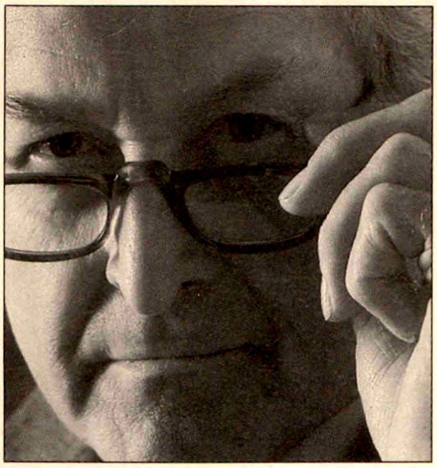
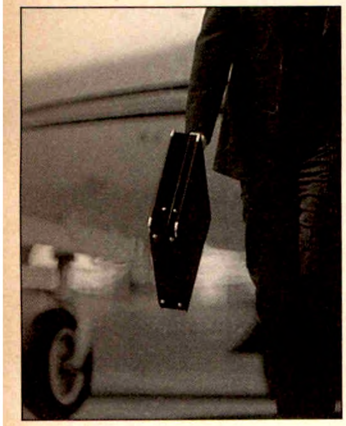
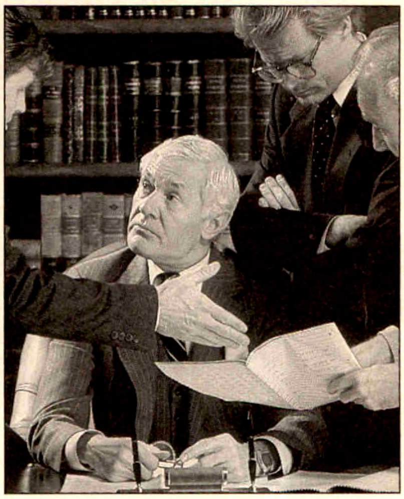
Book Reviews

Do you really think he's going to sit still for a sitz bath?







Hemorrhoid Case Study #1

Patient: 56-year-old business executive.

Symptoms: Profuse rectal bleeding.

Diagnosis: Patient had undergone a hemorrhoidectomy ten years previously. Complete colonoscopy revealed normal findings except for the recurrence of several symptomatic Grade 2 internal hemorrhoids.

Treatment: Patient's travel and work schedule precluded compliance with prescribed treatment of sitz baths and suppositories three times a day. A decision was made to use ULTROID.™ Two 6-minute treatments at 16 milliamps were administered over a one-week period. Patient tolerated maximum milliamperage well and reported no pain during or after treatment.

Result: Patient reported no disruption to his work schedule or lifestyle. Subsequent postprocedure follow-up indicated no recurrence of symptomatic bleeding.

Hemorrhoids: A Problem Worth Solving.

The evidence is overwhelming. Every year 123,000 Americans undergo painful hemorrhoidectomies.[1] Millions more suffer from symptoms of itching, bleeding, and tissue prolapse through the rectum.

Patients with symptomatic hemorrhoids want immediate relief and a real solution.

ULTROID™: A Clinically Proven Solution.[2]

Now with ULTROID, Microvasive® introduces the future of nonsurgical hemorrhoid management. It is a monopolar, low-voltage treatment modality, clinically evaluated on hundreds of patients. ULTROID works biochemically at the feeding vasculature of the hemorrhoid's base. It leaves no visible ulceration or scarring.

ULTROID: Safe, Painless, and Effective.

ULTROID is the only modality that works on all four grades of symptomatic internal and mixed hemorrhoids. It works without cauterization, without burning. It can be used in your office, without special patient preparation or anesthesia. And, with ULTROID, patients experience no postprocedure pain or lifestyle disruption.

ULTROID: The New Treatment of Choice.

Intraoperative Colonoscopy

JEFFREY L. COHEN, M.D., and KENNETH A. FORDE, M.D.

From the Department of Surgery, College of Physicians and Surgeons, Columbia University, and Presbyterian Hospital, New York, New York

From 1973 to 1985, we performed intraoperative colonoscopy on 68 patients with indications as follows: location of a previous polypectomy site (44%), inability to complete colonoscopy preoperatively (24%), locating nonpalpable polyps (13%), to define the source of lower gastrointestinal bleeding (4%), and to perform polypectomy (3%). Endoscopic evaluation influenced the outcome in 93% of the patients. There were two complications, both splenic capsular tears. Despite our increased ability to resolve several of the earlier indications for intraoperative colonoscopy by examination prior to celiotomy, there remains a significant role for intraoperative colonoscopy.

ENDOSCOPIC EXAMINATION of the colon is usually performed outside of the operating room. There are, however, occasional problems that may require intraoperative colonoscopy for successful surgical management. We have reviewed our experience with intraoperative colonoscopy in 68 patients during the period 1973–1985. During this time there has been a radical change in the attitudes of surgeons and gastroenterologists toward the role of flexible colonoscopy in the diagnosis and treatment of colonic disorders. Furthermore, the continued advancement in the quality of the instrumentation, as well as the enhanced skill of the endoscopist, has led to a redefinition of the indications for intraoperative colonoscopy. The changing experience is reflected in this report.

Materials and Methods

In the time period represented by this study, 4271 colonoscopic examinations have been performed by the Surgical Endoscopy Service of Columbia-Presbyterian Medical Center. The 68 intraoperative examinations represent, therefore, 1.6% of the total number of colonoscopies performed. Excluded from this analysis were patients who underwent total gastrointestinal tract endoscopy for chronic or recurrent bleeding of obscure origin. The colonoscopes employed for the examinations were those made by American Cystoscope Makers (ACM, Stamford, CT), Fujinon (Wayne, NJ), Olympus (Olympus Corp., New Hyde Park, NY), and Pentax (Orangeburg, NY).

Our technique for the performance of intraoperative colonoscopy has been described in detail.[1-3] After positioning the patient on the operating table with the thighs elevated by a couple of pillows, the tip of the colonoscope is gently inserted into the rectum and the instrument is then secured to the operating table. This posi-

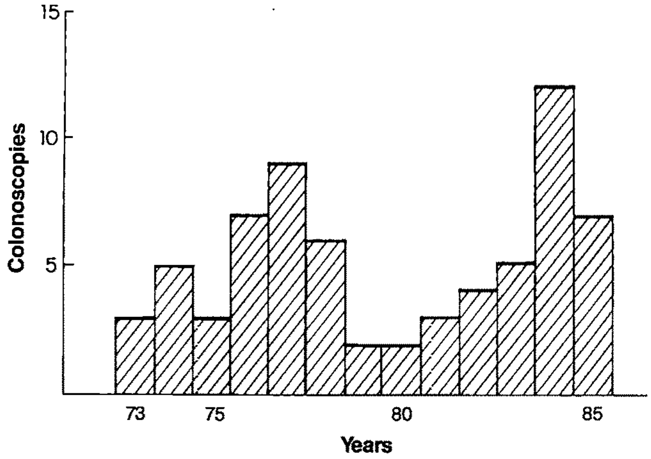

FIG. 1. Yearly incidence of intraoperative colonoscopy.

tioning allows adequate room for subsequent manipulation of the instrument. At celiotomy, the terminal ileum is occluded with a noncrushing clamp to prevent distention of the small intestine during the air insufflation necessary during passage of the colonoscope. With the aid and guidance of the operating surgeon, the endoscopist advances the instrument to the cecum. Lesions detected endoscopically can be marked with serosal sutures by the operating team.

Results

The yearly incidence of the performance of intraoperative colonoscopy is depicted in Figure 1. The biphasic nature of the experience is evident.

The overall indications for intraoperative colonoscopy for the entire time period of 1973–1985 are listed in Table 1.

Endoscopic evaluation of the colon at the time of operation was successful and influenced the outcome in 63 of the 68 patients (93%) in whom it was employed. Of the five failures, two were in the setting of active lower gastrointestinal bleeding, where the bleeding site could not be identified. The other three failures were technical inability to pass the colonoscope, inability to identify a polypectomy site, and inability to identify a colovesical fistula in one patient each.

TABLE 1. *Indications for Intraoperative Colonoscopy (N = 68)*

Indication	Number (%)
Location of previous polypectomy site	32 (44%)
Inability to complete colonoscopy preoperatively	16 (24%)
Location of nonpalpable polyps to define the limits of resection	9 (13%)
To define the source of GI bleeding	3 (4%)
To rule out synchronous lesions	3 (4%)
Polypectomy to limit the extent of resection	2 (3%)
Other	3 (4%)

The overall complication rate directly related to the procedure was 3%; both patients incurred splenic capsular tears, one of whom required a splenectomy.

Discussion

Over the last decade there has been a rapid expansion in the use of the flexible fiberoptic endoscope. This modality has become an essential tool in the surgeon's armamentarium. With the increased popularity of the endoscope, its uses have been limited only by the endoscopist's imagination. A natural extension of this technique by the surgical endoscopist has been in the operating room. Since the early 1970s, endoscopists have published sporadic reports of intraoperative colonoscopy and its possible indications.[3–6]

In our own early experience,[1] intraoperative colonoscopy yielded some degree of benefit in 27 of the 29 patients in whom it was employed. It should be pointed out, however, that several of these patients could have undergone preoperative colonoscopy had the endoscopist been involved earlier in the management of the patient. For this reason, as well as our increasing expertise in the use of the colonoscope, we believed that the need for intraoperative colonoscopy would decrease over time. It was therefore surprising that in reviewing the yearly incidence of intraoperative colonoscopies, an increase was seen over the past several years (Fig. 1). Intraoperative colonoscopy again comprised approximately 2% of our total yearly colonoscopic examinations. The reason for this later increased usage is to be found in the current indications.

When the indications are broken down into separate time segments representing the *early* and the *recent* period (Table 2), several trends are identified. If we look at the most frequent indications in both groups, the striking difference is that location of a previous polypectomy site has become the most frequent indication. That category alone represented 70% of the indications for intraoperative colonoscopy since 1970, as compared to the 25% for 1973–1979. This obviously reflects the changing orientation of both the medical and surgical communities toward the evaluation of gastrointestinal disease, with many more patients having undergone colonoscopic polypectomy prior to being seen by the surgeon. Despite reports by Ponsky and King[7] and Poulard et al.[8] there have been no articles documenting commonly employed methods of marking polypectomy sites at the time of their initial excision or subsequent preoperative colonoscopy. Repeating the colonoscopic examination prior to, rather than at the time of, operation may not be as rewarding in terms of localizing a polypectomy site to various parts of especially the sigmoid colon or in relation to the peritoneal reflection. These are areas of the colon where precise localization would be of great benefit to the surgeon, and even the use of fluoroscopy in the endoscopy suite if it is available may not be of universal accuracy.

As for the time limitation involved in the ability to visualize a polypectomy site, there was only one failure in our 32 attempts at identifying the site. This occurred in a patient whose intraoperative colonoscopy was performed eight days after polypectomy at another institution. Of the other 31 patients who were colonoscoped for this indication, the time delay ranged from 2 days to 8 weeks. While the findings at the polypectomy site can be quite variable, including ulceration, granulation tissue, or residual tumor, it can be expected from our experience that some evidence of a previous polypectomy may be demonstrable up to 6–8 weeks following initial colonoscopy.

Other less impressive but still important trends that were identified when comparing the early *versus* recent experiences was in the indications of inability to successfully colonoscope the patient preoperatively and for finding the source of gastrointestinal bleeding. There were significantly fewer patients since 1980 whom we were unable to colonoscope successfully in the endoscope suite. The four patients who underwent intraoperative colonoscopy since 1980 for this indication all had lesions visualized on barium enema which could not be seen by preoperative colonoscopy either secondary to adhesions or because of synchronous lesions. While the frequency of this indication is always somewhat dependent on referral patterns and the types of patients seen in one's practice, its incidence should continue to decrease as the experience of the endoscopist increases and the quality of the instruments improves.

Since 1980 we have not performed intraoperative colonoscopy for acute bleeding because this examination is much more successfully accomplished in the endoscopy suite, provided that the patient is hemodynamically stable. Two of our intraoperative failures were due to inability to identify sources of gastrointestinal bleeding. The ability to turn the patient and maneuver the colonoscope is quite inhibited by the patient's rigid positioning on the operating table. Ideally, all the resources of the endoscopist should be available in order to overcome the handicap of a colon filled with blood.[9] However, the technique of intraoperative endoscopic examination for acute bleeding remains an option for the endoscopist and surgeon.

Two patients on our service suffered complications as a direct result of intraoperative colonoscopy. Both complications were splenic capsular lacerations, one of which resulted in a splenectomy in addition to a colonic resection. In neither case was the colonoscopic examination especially difficult. It is possible that the intraoperative nature of the examination may have led to a false sense of security by the endoscopist. Bowden[10] similarly reported incurring one splenic hilar tear among 51 intraoperative endoscopies, although his occurred as a result of overdistention of the stomach from peroral introduction of the endoscope. Other complications not encountered in this study but reported on by others include prolonged ileus[10] and serosal laceration.[11] Most of the potential complications of intraoperative colonoscopy can be minimized by teamwork between the surgeons and the endoscopist as well as attention to detail during the procedure.

In conclusion, while the role of intraoperative colonoscopy has certainly undergone changes over the last decade, there are situations in which it provides a useful adjunct to the traditional methods of diagnosis and treatment of colonic diseases.

TABLE 2. *Indications for Intraoperative Colonoscopy (Early vs. Recent Periods)*

Indication	Early Period 1973–1979 (N = 35)	Recent Period 1980–1985 (N = 33)
Location of previous polypectomy site	9 (26%)	23 (70%)
Inability to complete colonoscopy preoperatively	12 (34%)	4 (12%)
Location of nonpalpable polyps to define the limits of resection	6 (17%)	3 (9%)
To define source of GI bleeding	3 (9%)	0 (0%)
Other	5 (14%)	3 (9%)

Villous Tumors of the Duodenum

SUSAN GALANDIUK, M.D., ROBERT E. HERMANN, M.D., DAVID G. JAGELMAN, M.D.,* VICTOR W. FAZIO, M.D.,* and MICHAEL V. SIVAK, M.D.†

From the Departments of General Surgery, Colorectal Surgery, and Gastroenterology,† Cleveland Clinic Foundation, Cleveland, Ohio*

Records of 32 patients with 34 villous and tubulovillous adenomas of the duodenum, treated at the Cleveland Clinic over the past 21 years, were reviewed. Twenty-two patients (69%) had complete resection of the adenoma; the incidence of malignancy was 47%. Five patients underwent a Whipple procedure; 4 patients had segmental resection of the duodenum; 12 had wide local excision of the adenoma; 1 had both a segmental resection and a local excision for two separate adenomas; and 5 patients had endoscopic excision alone. The remaining five patients underwent exploratory laparotomy alone or with palliative bypass procedures. A 28% recurrence rate was observed, all of these after segmental resection, local excision, or endoscopic excision. The highest recurrence rate was associated with local excision. The 2- and 5-year survival rates for patients with adenomas containing invasive cancer were 22% and 0%, respectively, compared to 87% and 87%, respectively, for benign adenomas (including those with carcinoma in situ). Twenty-two per cent of patients had intestinal polyposis syndromes. Duodenal adenomas were diagnosed a mean of 17 years after colectomy for polyposis, indicating the need for continued surveillance in these patients.

VILLOUS AND TUBULOVILLOUS ADENOMAS of the duodenum appear to behave in a manner similar to villous and tubulovillous adenomas of the colon and rectum, having both a high rate of recurrence after local treatment and a high incidence of malignancy. Villous and tubulovillous adenomas of the duodenum have been reported with increasing frequency over the last 15 years, probably because of the increasing use of upper gastrointestinal endoscopy for evaluation of patients with gastrointestinal complaints and for screening examination of patients with polyposis syndromes. Although the Whipple procedure remains the procedure of choice in treating adenomas containing invasive cancer, the selection of an appropriate procedure to treat benign villous and tubulovillous adenomas of the duodenum, especially those with carcinoma in situ, is controversial.

The purpose of this report is to review the Cleveland Clinic experience in treating 32 patients with villous and tubulovillous adenomas of the duodenum during the past 21 years and to determine the frequency of malignant change in these neoplasms, recurrence rates, and the effect of types of treatment on recurrence.

Patient Materials and Methods

The records of the Department of Pathology and the Department of General Surgery of the Cleveland Clinic Foundation from 1965 to 1986 were reviewed for all patients with villous and tubulovillous adenomas of the duodenum. Thirty-two patients with 34 adenomas were identified. Patient charts were reviewed, and data regarding adenoma size, location in the duodenum, type of surgery, pathology, and recurrence were analyzed. Lesions were classified as supra-ampullary, peri-ampullary, or infra-ampullary, depending on their location with respect to the ampulla of Vater. Only cases in which the adenoma was stated to arise from duodenal mucosa and had a significant villous component were accepted for this review. Statistical comparisons were made using Fisher's exact test and survival rates calculated using the life table method.[1]

The male:female ratio was 1:1, with a mean patient age of 60 years (range: 29–81 years). The most frequent presenting symptoms are given in Table 1. Other symptoms included diarrhea, anemia, fatigue, fever (second-

Submitted for publication: September 12, 1987.

ary to cholangitis from biliary obstruction), and recurrent episodes of pancreatitis.

The diagnostic procedures most frequently used were esophagogastroduodenoscopy, endoscopic retrograde cholangiopancreatography, barium swallow, CT scan of the abdomen, and percutaneous transhepatic cholangiography. In the remaining patients, diagnosis was made at operation, frequently after the patient had been referred from another hospital where cholecystectomy and common bile duct exploration had been performed without relief of symptoms.

The mean adenoma diameter was 3.7 cm with a range of 0.9–9 cm. Twenty-eight patients had only one duodenal adenoma. Four patients, all with familial polyposis, had more than one adenoma; one had a synchronous tubular adenoma near the ampulla of Vater and many fundic gland polyps in the stomach, another had two adenomas in the second portion of the duodenum, and a third (with Peutz-Jeghers syndrome) had a hamartoma of the third portion of the duodenum in addition to a villous adenoma. The fourth patient developed a second villous adenoma of the duodenum at a different site 4 years after prior treatment of an adenoma by segmental resection.

Eighty-eight per cent of the adenomas were located in the second portion of the duodenum. Most of these lesions were peri-ampullary. Two adenomas were in the first part and another two were in the third part of the duodenum.

A biopsy was obtained before operation in 24 patients. In 23 patients, this was performed at the time of upper gastrointestinal endoscopy, and in one patient at the time of a previous laparotomy in another hospital. Brush cytology was obtained in ten patients. Biopsy correlated with the final pathology in 17 patients (71%) but was falsely negative for adenocarcinoma in six (25%). There were no false-positives. In four patients (40%) cytology was falsely negative for adenocarcinoma. Final examination of post-treatment specimens revealed 19 benign adenomas, three of which contained carcinoma in situ. Invasive adenocarcinoma was present in 15 lesions.

Twenty-seven patients were treated by operation, and five patients had endoscopic polypectomy, either by snare or laser excision. The patients were operated on by five surgeons; the majority of procedures were performed by one surgeon (R.E.H.).

A Whipple procedure was performed in five patients. The ampulla was resected and required reconstruction in one of five patients undergoing segmental resection of the duodenum. Common bile duct and pancreatic duct-duodenal reconstruction was performed in 7 of 13 patients who underwent wide local excision of a periampullary adenoma.

TABLE 1. *Presenting Symptoms*

	No. of Patients	%
Jaundice	13	41
Weight loss	13	41
Epigastric pain	12	38
Melena/guaiac + stool	5	16
Partial intestinal obstruction	3	9
Asymptomatic	3	9

In two patients, unresectable carcinoma was present and choledochojejunostomy or choledochoduodenostomy performed. In three other patients, liver metastases were present; exploratory laparotomy only was performed in one patient and choledochojejunostomy in the other two.

Five patients underwent endoscopic removal of six adenomas. Three adenomas were removed by conventional snare excision and three by laser excision. Adenomas removed using the laser required two, two, and five laser sessions, respectively, until the lesions were completely removed. In one case, a biliary stent had to be inserted prior to adenoma excision in order to avoid ductal injury.

The mean adenoma size of patients undergoing local excision was 2.7 cm, 5.6 cm for segmental duodenal resection, and 4.4 cm (all malignant) for those having a Whipple procedure. No description of size was available for four of the six adenomas removed endoscopically.

Results

The mean hospital stay was 17.3 days, with a range of 3–39 days. One patient was treated endoscopically as an outpatient. The other four patients treated endoscopically were hospitalized a mean of 5.3 days (range: 3–8 days).

The overall hospital mortality rate was 3.5% (one death) with a postoperative morbidity of 56%. None of the patients undergoing a Whipple procedure died, but postoperative complications occurred in two of five patients (40%). One of the five patients who had segmental duodenal resection died postoperatively of acute hemorrhagic pancreatitis, the only death in this series. All five patients in this group had postoperative complications. Duodenotomy and wide local excision of the tumor had no mortality rates, but 62% of patients had postoperative complications. The only complication occurring in six endoscopic polypectomies was a 3 g/dL drop in hemoglobin in one patient, requiring admission for observation but no transfusion.

The complications that occurred in the group as a whole included postoperative bleeding requiring transfusion in seven patients, temporary duodenal fistula in three patients, and pancreatitis in two patients.

TABLE 2. *Local Recurrence by Primary Procedure*

	No. of Patients	%
Local excision	6/13	46
Endoscopic excision	2/6	33
Segmental resection	1/5	20

Invasive adenocarcinoma was present in 15 patients (47%). The most frequent site of involvement for both adenomas with and without malignant change was the periampullary duodenum. A dilated common bile duct did not always indicate malignancy; 86% of patients with cancer had a dilated common bile duct, but, conversely, only 63% of patients with a dilated bile duct had cancer. Size was also not an accurate predictor of adenocarcinoma ($p = 0.202$).

Villous and tubulovillous adenomas containing adenocarcinoma were treated by a Whipple procedure in five patients, segmental duodenal resection in two, wide local excision in three, and exploratory laparotomy with or without bypass in five patients. Of the 15 patients with adenocarcinoma, 6 are alive without evidence of cancer, 1 is alive with cancer, and 8 have died of carcinoma. The mean follow-up time for these patients was 16 months (range: 1–60 months).

Carcinoma in situ was present in three adenomas and severe dysplasia was found in another two. Four of these five adenomas were treated by local excision and one by segmental duodenal resection. The only recurrence in this group occurred after local excision of a 3-cm villous adenoma with carcinoma in situ, with positive margins of resection in the pancreatic duct. Recurrence was detected at 8 months and was treated by endoscopic biopsy (excision) revealing the presence of a recurrent adenoma with severe dysplasia. This patient is currently being followed by endoscopic examination and biopsies at 6-month intervals. None of the other patients with carcinoma in situ or severe dysplasia developed a recurrence.

TABLE 3. *Patient Follow-up*

	1 Year (%)	2 Year (%)	5 Year (%)
Patients with benign adenomas	94	87	87
Patients with invasive cancer	73	22	0
All patients	85	72	43

Recurrent adenomas have been diagnosed in 9 of 32 patients (28%), a mean of 12 months after operation or endoscopy (range of from 1 to 54 months). Six of these nine recurrences occurred after local excision, two after endoscopic laser excision, and one after segmental duodenal resection (Table 2). In those patients with recurrence, the initial adenoma was benign in six of nine patients. Two patients with recurrences after treatment of benign adenomas had adenocarcinoma in the recurrent lesion. Choledochoduodenostomy was performed in these two patients; all other patients with a recurrence underwent resection or endoscopic removal. Three patients died 29–69 months after diagnosis of the recurrent lesion, two of cancer and the other of unknown causes. Six patients are alive 6–19 months (mean 12 months) after treatment of recurrent benign lesions.

Sixty-two per cent of the patients have been followed for more than 1 year postoperatively. The mean time of follow-up is 22 months; however, 25% of patients have been treated less than 18 months prior to completion of this study. Table 3 lists patient status at follow-up. Survival rates, calculated using the life table method, are shown in Table 4 and Figure 1.

Seven of these 32 patients (22%) with villous or tubulovillous adenomas of the duodenum had an intestinal polyposis syndrome: six patients had familial polyposis coli and one patient had Peutz-Jeghers syndrome. The mean age in this subgroup of patients was 49 years, 12 years younger than the mean age of our patients without a polyposis syndrome. The mean adenoma diameter in this group was 4 cm, similar to that of the other patients. Patients with polyposis syndromes were the only patients with a history of previous polyps, all of these having been in the colon. Five patients had previously been treated by total proctocolectomy and end ileostomy, one patient by a subtotal colectomy and ileorectal anastomosis, and one patient (with Peutz-Jeghers) had undergone a partial colectomy. These procedures had been performed 2–32 years (mean: 17 years) prior to identification of the duodenal adenomas. Duodenal adenomas were diagnosed 14–33 years (mean: 24 years) after diagnosis of the polyposis syndrome. Two of these duodenal lesions were asymptomatic and were diagnosed on surveillance endoscopy. Adenocarcinoma was present in the villous adenoma in two of seven patients. In one patient, at operation metastatic disease was already present and a biliary-intestinal bypass was performed; in the other patient a Whipple procedure was performed, but the patient died of metastatic disease 13 months later. One patient had two benign villous adenomas of the duodenum occurring 4 years apart. The first was treated by segmental resection and the second by local excision. The remaining adenomas were all benign and were treated by endoscopic snare or laser excision. Follow-up studies have shown that two of the patients with polyposis syndromes developed new adenomas at sites other than those from which polyps had previously been removed at 20 and 36 months. Both of these were asymptomatic and were noted on routine surveillance endoscopy and removed endoscopically.

Discussion

Duodenal villous adenomas tend to be large lesions. In a previous review, 22 of 23 villous adenomas were greater than 3 cm in diameter[2]; this concurs with the mean adenoma diameter of 3.7 cm in this series. Although the incidence of adenocarcinoma in colorectal villous adenomas increases with increasing adenoma size, Kutin et al. found that this is not true for villous adenomas of the duodenum.[3,4] Our data support this view.

A 25–50% rate of cancer in villous adenomas of the duodenum has been reported.[3,5–8] In our series, the incidence of malignancy was 47% and the resectability rate was 64%. We concur with the opinion of others who have recommended that all villous adenomas of the duodenum be considered potentially malignant until proven otherwise.[9]

Pancreatoduodenal resection (Whipple) remains the operation of choice for patients with invasive periampullary carcinoma. Small lesions not adjacent to the ampulla of Vater and lesions with foci of carcinoma in situ may be treated by segmental duodenal resection or by wide local excision. Because of the magnitude of the Whipple procedure and its potential morbidity and mortality rates, we believe that this procedure is justified only in patients with invasive adenocarcinoma. Due to the small number of patients, no meaningful statement can be made regarding survival after pancreatoduodenectomy for villous adenomas with invasive malignancy. A recent review of patients with periampullary carcinoma treated by pancreatoduodenectomy at the Cleveland Clinic did, however, demonstrate that patients with papillary adenocarcinoma had a 5-year survival rate of 49% compared to 18% for patients with nonpapillary tumors.[10]

We have not observed a tendency for benign lesions to extend up the biliary or pancreatic ducts. At this time, we cannot recommend a Whipple procedure for benign lesions or for those with carcinoma in situ, as has been recommended by Ryan et al.[11]

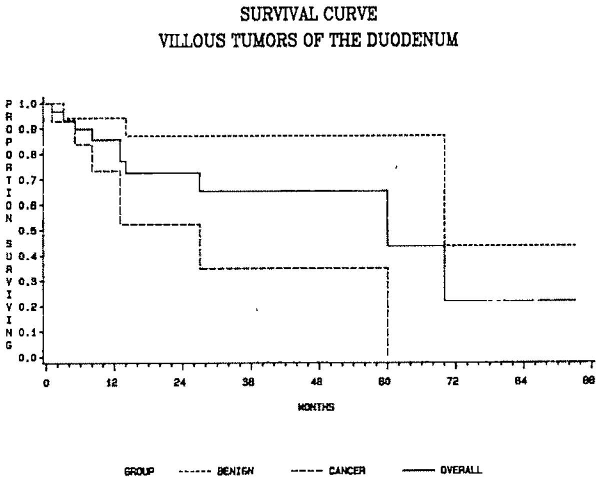

FIG. 1. Survival curves for all patients, for those with benign adenomas, and patients with adenomas containing invasive adenocarcinoma.

Our present recommendation for treatment is shown in Figure 2. It is based on examination of an excisional or endoscopic biopsy of the entire tumor since random biopsies are not reliable in detecting invasive adenocarcinoma. Endoscopic excision alone may be adequate treatment for benign lesions, but may be limited by the proximity of the biliary and pancreatic ducts. The ability to place biliary stents and perform sphincterotomies endoscopically has increased the number of lesions that can be treated this way, but more than one endoscopic treatment is frequently necessary. The use of a multipolar electrode (Bicap®, ACMI, American Cystoscope Manufacturer, Stamford, CT) or heater probe (Olympus) is preferred for ablation. A side-viewing endoscope is also essential for adequate visualization of the periampullary area. The rate of morbidity of endoscopic excision in this series was minimal, although hospitalization for observation was necessary in most patients.

Wide local excision involves removal of the lesion to the level of the submucosa and frequently requires operative reconstruction of the bile and pancreatic ducts to duodenal mucosa. Recurrence was common (6 of 13 patients) after local excision. The overall recurrence rate of 28% in our series was most likely related to the narrow margins obtained after a local resection because of the proximity of the bile and pancreatic ducts and the difficulty in determining clear margins because of the soft, friable nature of these adenomas. Continuing endoscopic surveillance at 6- to 12-month intervals permits the detection and treatment of recurrent lesions. The major danger lies in poor patient compliance. Two patients with benign lesions who did not return for periodic follow-up subsequently developed recurrent tumors with malignant change and died of cancer.

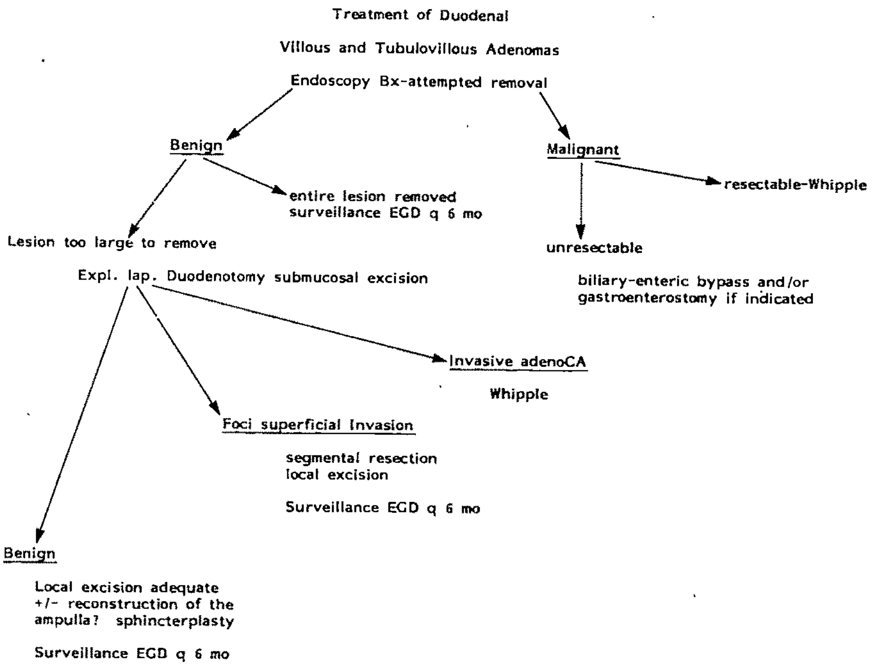

FIG. 2. Treatment strategy for duodenal adenomas.

Twenty-two per cent of our patients had intestinal polyposis syndromes. One patient in our series had Peutz-Jeghers syndrome. Although there are several reports of upper gastrointestinal malignancies in patients with Peutz-Jeghers syndrome, we are not aware of any reports of duodenal villous adenomas in these patients.[12–14]

Duodenal carcinoma is the most frequent extracolonic malignancy in patients with familial polyposis coli (FPC), reported in 2–12% of patients.[3,15,16] Prophylactic colectomy and ileorectal anastomosis or proctocolectomy have led to longer survival in these patients and have given them time to develop a periampullary carcinoma.[17,18] Many investigators believe that Gardner's syndrome represents a *pleiotropic manifestation* of a genetic defect with a predisposition of the entire gastrointestinal tract to develop polyps.[15,16,19–22] Fundic gland polyps have been reported in these patients, as well as a 41–100% incidence of synchronous duodenal polyps.[15–18,20,22–24] Polyps may easily be missed by barium swallow examination, while endoscopy permits direct vision and the ability to biopsy. In the majority of cases, the papilla has a nodular or granular yellow to white appearance, and the affected mucosa appears lighter than normal.[15,19,20] In some patients biopsies of normal appearing ampullae may disclose adenomatous changes.[23] For this reason, some investigators recommend routine biopsy in these patients.[24] Few papers on duodenal polyps in patients with FPC have reported on the types of adenomas present in these patients. The number of tubular adenomas in our FPC patients at the Cleveland Clinic has greatly exceeded the number of villous adenomas found. In a recent prospective study, only 21% of FPC patients with duodenal adenomas had tubulovillous or villous adenomas.[25]

The mean time interval from diagnosis of FPC to diagnosis of a periampullary tumor in our series was 24 years. In one report, the mean age of FPC patients without duodenal adenomas was 29 years; it was 34 years for patients with FPC and duodenal adenomas and 45 years for FPC patients with periampullary carcinoma, suggesting an adenoma-carcinoma sequence in the duodenum similar to that in the colon and rectum.[18,24]

Patients being evaluated for FPC should have a routine surveillance esophagogastroduodenoscopy (EGD). If negative, this procedure is repeated annually. If adenomas are found, they should be removed and endoscopic follow-up performed at 6-month intervals. The only patients in this series that developed subsequent new villous adenomas of the duodenum were polyposis patients. The mean 17-year delay between colectomy and diagnosis of the duodenal adenoma indicates that long-term follow-up of these patients is necessary.

Hirschsprung's Disease

Identification of Risk Factors for Enterocolitis

DANIEL H. TEITELBAUM, M.D., STEPHEN J. QUALMAN, M.D., and DONNA A. CANIANO, M.D.

From 1975 to 1985, 80 infants and children were treated at a major pediatric hospital for Hirschsprung's disease, 19 (24%) of whom developed enterocolitis. In 9 neonates (18%) and 4 infants (29%) enterocolitis was present at diagnosis of Hirschsprung's disease, while 4 children acquired enterocolitis following a pull-through procedure. Significant risk factors for development of Hirschsprung's-associated enterocolitis (HAEC) were delay in diagnosis beyond 1 week of age and the presence of trisomy 21. HAEC did not occur more frequently in patients with long-segment aganglionosis, nor did an initial episode of HAEC confer a higher risk of recurrent enterocolitis. HAEC following a pull-through procedure was correlated with an anorectal stricture in three of four cases. Although neonates with HAEC had a low mortality rate (5%), their morbidity rate was 30% and their hospitalization was twice as long as neonates without enterocolitis.

Despite significant advances in the recognition, diagnosis, and operative management of Hirschsprung's disease, enterocolitis remains its major source of morbidity and mortality.[1] Historically, the incidence of Hirschsprung's-associated enterocolitis (HAEC) has approached 50% with a mortality rate of 30%.[2] In recent surveys of 2824 infants and children with Hirschsprung's disease in North America and Japan, HAEC occurred in nearly one fourth of patients, with a mortality rate between 6% and 30%.[3,4]

This study evaluates the occurrence of enterocolitis in 80 infants and children treated for Hirschsprung's disease during the last decade at a major pediatric center. Factors associated with the development of enterocolitis are identified and the medical and economic impact of HAEC is analyzed.

From the Division of Pediatric Surgery, the Department of Surgery, and the Department of Pathology, Ohio State University College of Medicine, and the Children's Hospital, Columbus, Ohio

Methods

The charts of all patients (80 infants and children) initially treated for Hirschsprung's disease at the Children's Hospital, Columbus, OH between 1975 and 1985 were reviewed. Factors evaluated were sex, age at diagnosis, level of aganglionosis, familial history of Hirschsprung's disease, presence of associated anomalies, signs of HAEC (fever, distention, diarrhea), symptoms of HAEC (prostration, lethargy, crampy abdominal pain), positive cultures (blood, stool, peritoneal), type of colostomy and pull-through procedure, development of HAEC in relation to operative treatment, complications of treatment for HAEC, length and cost of hospitalization, and mortality rate.

Diagnosis of HAEC was made on the clinical findings of abdominal distention, diarrhea, and temperature greater than 38 C.[5,6] Statistical analysis was done using either a paired or unpaired t-test, or chi square analysis. Statistical significance was given for $p < 0.05$.

Results

Total Group

The patients included 60 males (75%); a family history of Hirschsprung's disease was present in 3 (4.7%). Diagnosis of Hirschsprung's disease was made at 30 days of age or less in 51 patients (64%); 31–180 days in 14 (18%); and over 6 months in 15 (18%). The level of aganglionosis was confined to the distal rectum in 2 (2%); rectosigmoid in 66 (83%); transverse colon in 5 (6%); and total colon in 7 (9%).

Submitted for publication: August 17, 1987.

Trisomy 21 was present in 13 patients (16%). Ten children (77%) with trisomy 21 had other associated congenital anomalies including cardiac (6), central nervous system (1), and gastrointestinal (3). In the 67 patients without trisomy 21, associated congenital anomalies occurred in 16 (24%): cardiac (4), central nervous system (5), genitourinary (2), maxillofacial (3), and skeletal (2).

Initial operative procedures included sigmoid colostomy (60), transverse colostomy (5), ileostomy (8), anal myectomy (2), and cecostomy (1). Three children were treated with daily saline rectal washouts of whom two underwent a subsequent pull-through and one continues nonoperative management. Fifty-nine patients have undergone a definitive pull-through procedure: Duhamel (40); Swenson (10); Soave (7); and anal myectomy (2).

HAEC Group

Nineteen of the 80 patients developed at least one episode of HAEC, an incidence of 24%. The level of aganglionosis in patients with HAEC was confined to the rectosigmoid in 16 (85%), transverse colon in 1 (5%), and total colon in 2 (10%). Enterocolitis did not occur at a significantly more frequent rate in patients with longer levels of aganglionosis: 24% for rectosigmoid aganglionosis, 20% for transverse colon aganglionosis, and 29% for total colon aganglionosis.

Of the 19 patients with HAEC, 13 were neonates and infants whose presenting diagnostic sign of Hirschsprung's disease was enterocolitis. Two infants developed HAEC after decompressive enterostomies, while four children acquired enterocolitis after a pull-through procedure. Two of the 13 infants with HAEC at diagnosis developed recurrent enterocolitis (15%), one after colostomy and one after pull-through. Three of the four children with HAEC following a pull-through procedure had recurrences.

Six of the 19 patients with HAEC had trisomy 21 (32%), although trisomy 21 occurred in only 16% of the 80 patients in the total group with Hirschsprung's disease. A significantly ($p < 0.05$) larger proportion of patients with trisomy 21 developed HAEC compared to patients without trisomy 21 (Table 1).

The clinical signs and symptoms of HAEC were abdominal distention (19), diarrhea (19), and temperature greater than 38 C (16) (Table 2). Bloody stools occurred in four patients. Five children had positive blood cultures (27%): *Escherichia coli* (4) and *Enterobacter* and *E. coli* (1). *Bacteroides fragilis* and *E. coli* were cultured from one child's peritoneal fluid. Six patients had infections with enterocyte-adherent organisms based on tissue specimens and tissue assays: toxigenic *E. coli* (4), toxigenic *Clostridium difficile* (1), and *Cryptosporidium* (1).

HAEC in Neonates and Infants

Of the 13 patients with HAEC at diagnosis, 9 were neonates less than 30 days of age and 4 were infants between 1 and 6 months of age. The 9 neonates with HAEC at diagnosis represented 18% of the 51 neonates with Hirschsprung's disease in the total group. The mean age at diagnosis for the neonates with HAEC was 16.6 ± 11.3 d (mean ± SD), significantly later ($p < 0.01$) than the mean age at diagnosis of 4.6 ± 6.5 d for the neonates without enterocolitis. In addition, significantly more neonates presented with HAEC after 10 days of age as compared to neonates without enterocolitis (Fig. 1). The mean age for passage of meconium was 53 ± 12 h in the neonates with HAEC and 40 ± 4 h in neonates without HAEC, a significant difference at $p < 0.05$.

Seven of the 9 neonates with HAEC were considered to have a significant delay in diagnosis. In these patients

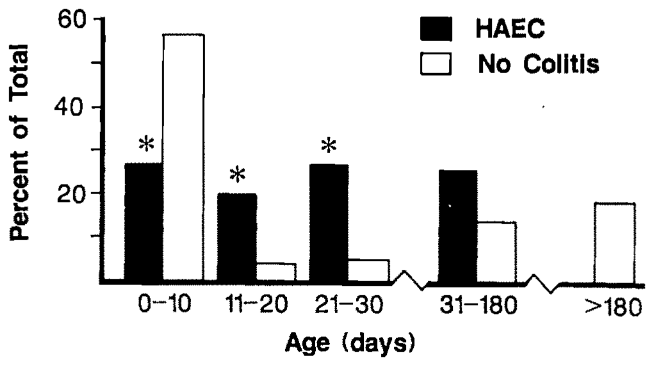

FIG. 1. Mean age at diagnosis of Hirschsprung's disease in days. Enterocolitis was present in significantly more neonates (*$p \leq 0.05$) diagnosed after 10 days of age.

Library

a history of abnormal or infrequent passage of stools followed by abdominal distention, lethargy, and diarrhea had occurred for 1 or 2 weeks prior to referral. Two neonates became acutely ill and were diagnosed promptly. The first, a 2-day-old, developed emesis and abdominal distention; at laparotomy he had enterocolitis and a cecal perforation. The second neonate, a 6-day-old with trisomy 21 and cardiac anomalies, was referred after 24 hours of foul-smelling diarrhea and lethargy.

Four infants (29%) presented with HAEC between 50 and 70 days of age. In three patients a history of severe constipation with abdominal distention was elicited. The fourth infant had multiple congenital anomalies including trisomy 21, cardiac disease, duodenal stenosis, and infralevator imperforate anus. Constipation persisted following a perineal anoplasty with the acute onset of abdominal distention and diarrhea.

Three neonates with HAEC developed complications before or after colostomy (30%). One infant sustained a cecal perforation secondary to severe colitis, which was not recognized at the initial operation for sigmoid colostomy. On the third postoperative day he developed an evisceration and required reexploration and ileostomy. One neonate sustained a perforation of the sigmoid colon during rectal saline washouts prior to colostomy. A third infant required revision of a sigmoid colostomy for retraction of the stoma.

Neonates with HAEC at diagnosis were hospitalized an average of 25 days compared to an average of 13 days for neonates without HAEC ($p < 0.05$). The average hospital cost for infants with HAEC ($17,810) was significantly greater ($p < 0.01$) than for infants without HAEC ($7,328).

Three infants with HAEC died, all of whom had trisomy 21. However, only one death was directly attributable to HAEC, a mortality rate of 5%. A 2-month-old infant had undergone a right transverse colostomy at 22 days of age for clinical HAEC. He recovered but returned 6 weeks later moribund with HAEC; autopsy confirmed diffuse enterocolitis and a perforation in the ascending colon 5 cm proximal to the colostomy. A second infant with an endocardial cushion defect who had presented with HAEC and recovered following sigmoid colostomy died from progressive cardiac failure. The third infant suffered a fatal aspiration pneumonia having recovered from HAEC.

HAEC Following Operative Procedures

Two infants developed enterocolitis following initial operation: colostomy in one and ileostomy in the other. The first patient was diagnosed at 24 hours of age with Hirschsprung's disease, trisomy 21, and an endocardial cushion defect; a sigmoid colostomy was performed. He returned at 1 month of age with HAEC and recovered without complication. Recurrent enterocolitis has not developed; definitive pull-through has been deferred because of severe cyanotic cardiac disease.

The second infant underwent an ileostomy for total colonic Hirschsprung's disease at 18 days of age. Eight months later he developed enterocolitis and recovered after prolonged total parenteral nutrition. This patient awaits a definitive pull-through procedure.

Five children acquired HAEC following a pull-through procedure, of whom four had no previous episodes. Three patients experienced two or more episodes of HAEC within 2 years of the pull-through. All children with post–pull-through HAEC were evaluated by barium enema, proctoscopy and sigmoidoscopy, colonic biopsy, or anal manometry. In three patients an anorectal stricture was diagnosed: one following a Swenson pull-through complicated by anastomotic leak, and two after uncomplicated Soave and Swenson procedures. All required secondary operations including anal dilatation (1) and internal sphincterotomy (2). A fourth child with severe psychomotor retardation developed multiple episodes of HAEC following an uncomplicated Duhamel pull-through and required an end-ileostomy for ultimate relief. A fifth patient with trisomy 21 developed *Cryptosporidiosis* enterocolitis 2 years after a Duhamel pull-through and recovered without further episodes.

Discussion

Prompt diagnosis of Hirschsprung's disease and expeditious placement of a decompressive enterostomy above the level of aganglionosis have been considered critical factors in the prevention of enterocolitis.[5] Although most pediatric surgical centers strictly adhere to these guidelines, HAEC continues to be a serious, often life-threatening condition. Our study underscores many accepted features of HAEC and, more importantly, identifies potential risk factors for its development.

HAEC has been characterized by an increased incidence and high mortality rate in the neonatal period. In 1962 Bill and Chapman[2] noted that neonates comprised 88% of patients with preoperative HAEC and accounted for all of the deaths. The 1975–1976 survey of 1196 infants and children by the Surgical Section of the American Academy of Pediatrics reported enterocolitis in 15% of patients at diagnosis of Hirschsprung's disease of whom one fourth were less than 3 months of age.[3] The Surgical Section survey concluded that the diagnosis of Hirschsprung's disease should be established by 1 month of age to reduce the incidence of enterocolitis.

In our series 51 of the 80 patients (64%) were diagnosed within the first month of life, yet HAEC occurred in 9 (18%) of the neonates. Closer evaluation discloses that the average age at diagnosis for neonates with HAEC was 16 days compared to 4 days for neonates without enterocolitis. Furthermore, three fourths of our patients with enterocolitis at diagnosis were less than 1 month of age. Clearly, patients in our series required diagnosis of Hirschsprung's disease early in the neonatal period, as soon as the first week of life, to decrease their risk of enterocolitis.

Three recent series confirm the importance of diagnosis in the early neonatal period. Grosfeld et al.[6] in 1978 reported 89 patients with Hirschsprung's disease of whom 34 (38%) were diagnosed under 1 month of age and 7 (20%) experienced neonatal enterocolitis. In Polley and Coran's 1986 series of 35 neonates with Hirschsprung's disease,[7] the average age at diagnosis was 9.9 days, yet the incidence of enterocolitis was 11%. Twenty-six neonatal cases of Hirschsprung's disease were reviewed by Klein et al.[8] in which diagnosis and decompressive enterostomy were accomplished by 2 weeks of age and no cases of HAEC were documented. Our data in conjunction with these reports substantiates the necessity of diagnosis of Hirschsprung's disease early in neonatal life.

If Hirschsprung's disease requires diagnosis within the first several days of life to decrease the risk of enterocolitis, then a high index of suspicion and aggressive evaluation are necessary. The medical histories of the 51 neonates with Hirschsprung's disease in our series identify an abnormal stooling pattern characterized by delayed meconium passage, infrequent stools, or no spontaneous stools. As Swenson et al.[9] stated in 1973, ". . . it is clear that failure to pass meconium within the first 24 hours of life, . . . is the objective information which should alert the physician to the possibility of congenital megacolon." Implementation of Dr. Swenson's now classic observation would have most likely eliminated all but two of our neonatal and infant cases of HAEC.

The well-recognized association of trisomy 21 and Hirschsprung's disease has been reported in 3% of cases,[4,9] while more recent series note a 15% occurrence.[6,7] The higher incidence of trisomy 21 in our series (16%) allows for several observations. First, patients with trisomy 21 comprised one third of all cases of enterocolitis. Second, 46% of the infants and children with trisomy 21 developed HAEC in comparison to only 19% of patients without trisomy 21. Third, associated anomalies were present in three fourths of the patients with trisomy 21 but in only one fourth without trisomy 21. Fourth, the three deaths in our series occurred in patients with trisomy 21; one death was directly attributable to HAEC. The other two infants died of associated problems following recovery from an episode of enterocolitis. Based on these findings, we believe that Hirschsprung's disease in an infant or child with trisomy 21 should be viewed as a strong risk factor for development of enterocolitis. Patients with trisomy 21 have marked deficiencies in T cell-mediated cytotoxicity and in interferon production[10] and possible derangements in humoral immunity.[11] It may be that infants and children with trisomy 21 are more susceptible to HAEC and less immunologically capable of recovery. No study has addressed the functional integrity of gastrointestinal immunity in patients with trisomy 21 and Hirschsprung's disease.

Enterocyte-adherent organisms were present in the colonic specimens in one third of our patients with HAEC. These organisms were not identified in the tissue specimens of patients without enterocolitis. Enterocyte-adherent organisms may have a role in the pathogenesis of HAEC, or the presence of enterocolitis may predispose the intestinal mucosa to attachment of enterocyte-adherent organisms. *Clostridium difficile* toxin has been isolated more frequently from young children with HAEC than from healthy patients with Hirschsprung's disease,[12] suggestive of a possible causal relationship.

Previous authors have reported that infants and children with long-segment aganglionosis are at an increased risk to develop enterocolitis.[3,4] Patients in our study with longer levels of aganglionosis (transverse and total colon) did not acquire HAEC more frequently than patients with rectosigmoid disease. Most likely, this discrepancy relates to the majority of our cases of long-segment aganglionosis achieving diagnosis and treatment in the neonatal period.

An initial episode of enterocolitis at diagnosis of Hirschsprung's disease has been considered a predisposing factor for further episodes.[5,9] However, recurrent HAEC occurred in only two cases (15%) in our series, one of which developed after a pull-through procedure complicated by an anorectal stricture. In the second case an infant with trisomy 21 acquired a diffuse, fatal enterocolitis 6 weeks following recovery from his first episode of HAEC.

Enterocolitis acquired after a pull-through procedure was most frequently the result of an anorectal stricture in our series. Standard diagnostic investigation including barium enema, rectal biopsy, and anal manometry was helpful in elucidating the etiology of the dysfunctional pull-through procedure. Following appropriate secondary operations to relieve the anorectal stricture, no child suffered additional episodes of HAEC.

Neonatal enterocolitis at diagnosis of Hirschsprung's disease imposes the risk of increased morbidity and extended hospitalization. One third of the neonates with HAEC in our series experienced a major complication requiring a second operative procedure. The dilated, thin-walled, and friable colon with enterocolitis must be handled with meticulous, gentle technique, and the colostomy must be carefully constructed to avoid postoperative evisceration and stomal prolapse. Neonates with HAEC were hospitalized twice as long as neonates without enterocolitis, and they incurred significantly higher medical expenses.

The low mortality rate of 5% for patients with HAEC in our series compares favorably with other reports.[3,5] This low mortality rate is misleading, however, because two infants died from other causes (cardiac disease and aspiration) immediately after recovery from an enterocolitis episode.

We conclude that enterocolitis continues to be a major cause of morbidity and mortality in infants and children with Hirschsprung's disease. Elimination of neonatal enterocolitis requires diagnosis of Hirschsprung's disease within the first several days of life. Significant risk factors for HAEC include a delay in diagnosis beyond 1 week of age and the presence of trisomy 21. Although neonates with enterocolitis have a longer and costlier hospitalization, recovery without recurrent episodes of HAEC can be anticipated for most patients.

Acknowledgments

The authors gratefully acknowledge William D. Gariott for technical assistance and Mrs. Karen Hansley for preparation of the manuscript.

INFECTION IN THE ELDERLY PATIENT

"NEPHROTOXICITY LIMITS THE CLINICAL UTILITY OF AMINOGLYCOSIDES."[1]

AZACTAM®

AZTREONAM

IN ELDERLY PATIENTS— GRAM-NEGATIVE EFFICACY WITHOUT AMINOGLYCOSIDE TOXICITY

AZACTAM®
AZTREONAM
FOR INJECTION

CLINICAL EFFICACY PROVEN IN STUDIES WITH NEARLY 300 ELDERLY PATIENTS[2-9]

- Efficacy comparable to aminoglycosides, with excellent activity against a wide range of susceptible gram-negative aerobic organisms, including *Pseudomonas aeruginosa*[2-4]

SUPERIOR SAFETY PROFILE*[2,3,10]– ESPECIALLY IMPORTANT IN ELDERLY PATIENTS

- Does not cause nephrotoxicity†[10-13]
- Does not cause ototoxicity[10,11]
- Requires no costly routine blood monitoring‡
- Avoids the costs that nephrotoxicity adds to all patients on aminoglycoside therapy (average $183/patient)[14]

*Dosage adjustment, based on estimated creatinine clearance, may be necessary in elderly patients.

For a discussion of INDICATIONS AND USAGE (including susceptible organisms), CONTRAINDICATIONS, PRECAUTIONS, and ADVERSE REACTIONS, please consult brief summary on adjacent page.

†Demonstrated in animal studies, and in human volunteer studies involving 36 subjects. In clinical trials involving 4,570 subjects, transient elevations in serum creatinine were rarely observed.

‡Renal function should be monitored when AZACTAM (aztreonam) is used concomitantly with aminoglycosides. In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy.

INSTEAD OF AMINOGLYCOSIDES...
ESPECIALLY IN ELDERLY PATIENTS

ACT **AZACTAM**®
AZTREONAM

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION—AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a otally synthetic bactericidal antibiotic with activity against a wide specrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different rom other beta-lactam antibiotics.

AZACTAM For Injection is a sterile nonpyrogenic white powder, containing approximately 780 mg L-arginine per gram of aztreonam, or intramuscular or intravenous use following constitution. The powder is sodium-free. Aqueous solutions of aztreonam have a pH in the ange of 4.5 to 7.5.

NDICATIONS AND USAGE—Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causaive organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of he susceptibility testing are available; subsequently, appropriate anibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the followng infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escheichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca**, *Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections**, including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis**, *Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections**, includng those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae*, and *Citrobacter* species*. **Intra-abdominal Infections**, including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae**, *Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections**, ncluding endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae**, *Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is efective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy—Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS—Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS—Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS—General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy—Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers—Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use—Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS—Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity: *Hypersensitivity*—anaphylaxis. *Hematologic*—pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*—abdominal cramps; rare cases of *C. difficile*-associated diarrhea or gastrointestinal bleeding have been reported. *Dermatologic*—purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*—hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*—one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*—hepatitis, jaundice. *Nervous System*—seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*—muscular aches. *Special Senses*—tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*—vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*—weakness, headache, fever, malaise.

Adverse Laboratory Changes—Those reported without regard to drug relationship during clinical trials were: *Hepatic*—elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*—increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*—increases in serum creatinine.

OVERDOSAGE—If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION—Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED—AZACTAM For Injection (Aztreonam For Injection) is supplied in single-dose 15 mL vials containing **500 mg, 1 g** or **2 g** per vial, and in single-dose 100 mL intravenous infusion bottles containing **500 mg, 1 g** or **2 g** per bottle.

Consult package insert before prescribing AZACTAM (aztreonam).

A New Mechanical Device for Circular Compression Anastomosis

Preliminary Results of Animal and Clinical Experimentation

RICCARDO ROSATI, M.D., CARLO REBUFFAT, M.D., and GIUSEPPE PEZZUOLI, M.D.

From the First Surgical Clinic, University of Milan, Milan, Italy

The authors report the preliminary results obtained in animal and clinical experimentation of a new mechanical device for circular anastomosis which they have developed. It is a gun that places an apparatus consisting of three polypropylene rings that, through the compression among them of the severed edges of the bowel, realize a sutureless anastomosis and are spontaneously evacuated. Fifty-eight colonic anastomoses were performed in dogs with this device; 23 stapled colonic anastomoses were also executed concurrently. Forty-four animals underwent a relaparotomy to remove the colonic specimen containing the anastomoses. Bursting pressure and the histologic features of the anastomoses were evaluated at different time intervals after operation. A good healing of all compression anastomoses was observed, thereby allowing them to initiate the experience in humans. Thirteen anastomoses (6 colorectal extraperitoneal, 1 colorectal intraperitoneal, 5 colocolonic, 1 ileorectal) were performed at the 1st Surgical Department, Milan University. One subclinical leakage (7.7%) spontaneously healed in a few days. No stenoses were observed.

THE USE OF compression anastomotic devices in the intestine as a temporary support to the tissue to allow for a natural healing process, has been known since the last century. Denans,[1] in 1826, invented the first compression device, thus starting a new technology that would form the basis for all future mechanical devices for anastomosis. Dr. Murphy,[2] in his original article in 1892, outlined the following: "What are the best means and methods of producing agglutination of surfaces and preventing subsequent contraction at the point of adhesion? If means can be divised—1, to hold surfaces in contact; 2, while in contact to provide a speedy and permanent adhesion of the surfaces; 3, to keep an opening sufficiently large for the free passage of intestinal content; 4, to produce, as a result, a cicatrix that will not contract to any greater extent, and by the contraction produce complete or partial obstruction—we will overcome the great barriers that still remain between us and ideal success in intestinal surgery." Murphy's "anastomotic button" was then introduced as the solution of the problems encountered in hand-sewn anastomoses. This procedure proved to be safe because the force produced by the button was distributed around the entire circumference of the anastomosis producing a watertight seal. The natural healing of this anastomosis caused the whole button to be eliminated. Thus no foreign bodies, which all induce stenosis, were left at the anastomotic site.

Nevertheless, the Murphy button and other compression devices[2-4] received limited acceptance throughout the surgical community. This was partially due to the fact they were difficult to use because they were placed manually with considerable bowel manipulation.

Recently, a device that performs compression anastomosis has been developed in the Soviet Union showing good clinical results.[5] With such a resurgence of interest on this matter, we developed and experimented a new mechanical device that realizes compression anastomoses placing endoluminally an apparatus consisting of three polypropylene rings. This paper presents the preliminary results we have obtained in animal experimentation in dogs and the initial human application of this device.

Methods

Materials

The anastomotic apparatus object of this paper consists of three molded polypropylene rings. These are an outer, an intermediate, and an inner ring (Fig. 1). They are carried by a gun that introduces them into the bowel, realizes their assemblage and their automatic disengage-

Submitted for publication August 27, 1987.

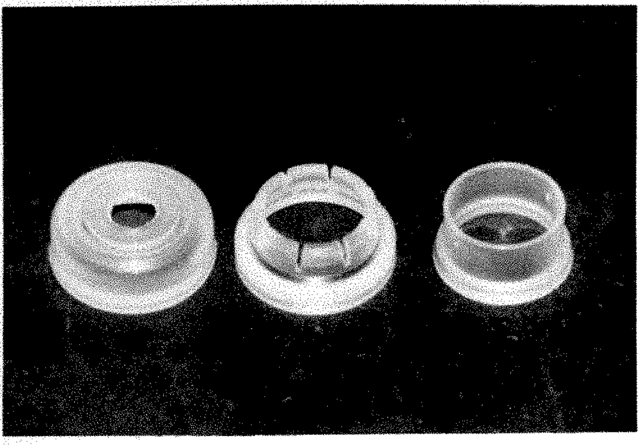

FIG. 1. The three rings of the anastomotic apparatus shown are from left to right: the outer, the intermediate, and the inner.

ment, being subsequently removed. The outer ring has the shape of an overturned bowl: it is stiff and it can hold, into its concavity , the conic-shaped intermediate ring that has an upper portion with multiple longitudinal slots. The inner cylindrical ring is also stiff. Once the intermediate ring is inserted into the outer ring, which is an easy maneuvre for the conic shape of the former, the assemblage of the system is realized when the inner ring is forced and fits into the intermediate ring. Thus, the upper portion of the latter, which is extensible for the longitudinal slots, expands while clinging into the concavity of the outer ring. The system, which realizes the compression of the bowel ends between the internal surface of the outer ring and the external surface of the intermediate ring, forms a firm, perfectly tight block. Two different sizes of rings are currently available: 30 mm and 25 mm outer diameter.

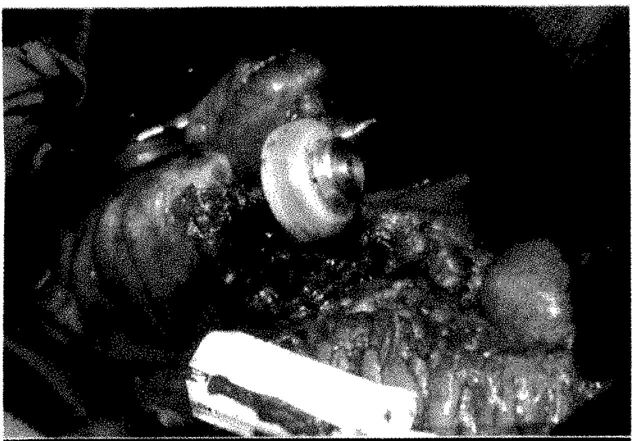
The gun carrying the anastomotic apparatus is composed of a head portion consisting of the ring holders and of a circular blade, a middle part consisting of coaxial tubular members that transmit the movements needed to realize the assemblage and the expulsion of the rings, and a body consisting of the handle and of the mechanisms regulating these movements.

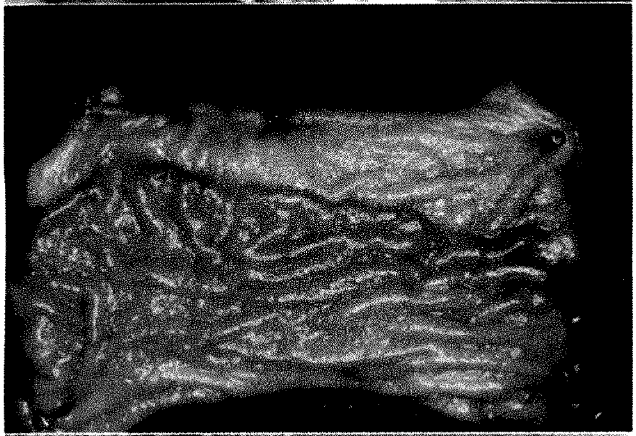
The intermediate ring is secured on the head that contains, just behind it, the inner ring. The outer ring is installed on the central shaft as the staplers anvil. To allow the assemblage and the expulsion of the rings, the outer ring is brought to a settled distance of 1.2 mm from the intermediate ring. By operating the lever of the gun, a series of movements is produced that causes the assemblage of the rings that cling together, and their automatic expulsion by means of a circular blade that, together with the tissue edges tied by the purse-string sutures, cuts also the outer ring at its joint to the central shaft. The extraction of the gun does not require any additional maneuvre, thus avoiding dangerous tractions on the anastomosis. The inner diameter of the anastomotic apparatus then results in 17.5 mm for the bigger rings and 12.5 mm for the smaller rings.

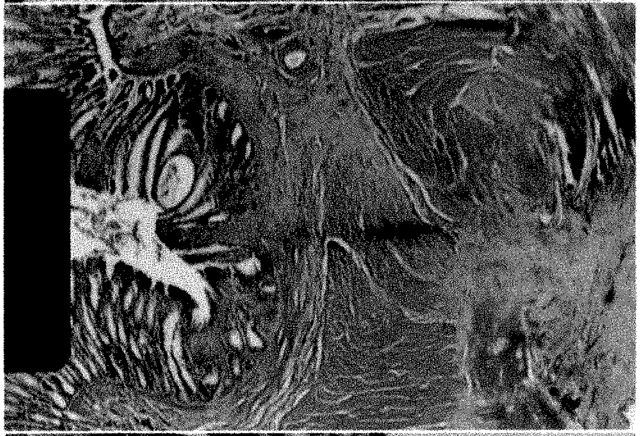
The surgical technique needed for the use of this gun, that allows the realization of end-to-end and end-to-side anastomoses, is similar to what is currently done when using staplers.[6] A colorectal anastomosis is an example of this technique. After removal of the rectum and sigmoid, the proximal colon is prepared by removing paracolonic fat and devascularizing it 1.5 cm from the severed edge where a purse-string suture has been previously placed. The gun is then lubricated with sterile lubricating oil and introduced transanally. The gun is slid into the bowel until the outer ring has exited from the rectal stump. Its central shaft, carrying the outer ring, is then extended and the distal purse-string suture is tied drawing the tissue around the intermediate ring (Fig. 2). The outer ring is then inserted into the colonic stump and the proximal purse-string suture is tied around the central shaft drawing the tissue over the outer ring. The central shaft is driven backward approximating the outer ring to the settled distance of 1.2 mm from the intermediate ring. During the approximation of the two anastomotic ends, care must be taken to avoid kinking of the bowel and to have a good serosa-to-serosa interface. Next, the gun is fired by operating the handle. This causes simultaneous assemblage of the rings, expulsion of the entire anastomotic apparatus, and disengagement of the gun from the anastomosis. The two tissue "doughnuts" cut by the circular blade must be, as for staplers, carefully inspected for completeness to ensure that the tissue ends are comprised between the rings. The anastomosis is achieved in this manner leaving only the three plastic rings at the anastomotic site. A drain, if necessary, should not be placed directly in contact with the anastomosis. This avoids possible decubitus lesions of the colonic wall that could be compressed between two stiff bodies: the rings inside the lumen and the drain tube outside. The rings will fall into the bowel lumen and will be evacuated. Their detachment takes place when a natural healing of the anastomosis is achieved outside the compressed area.

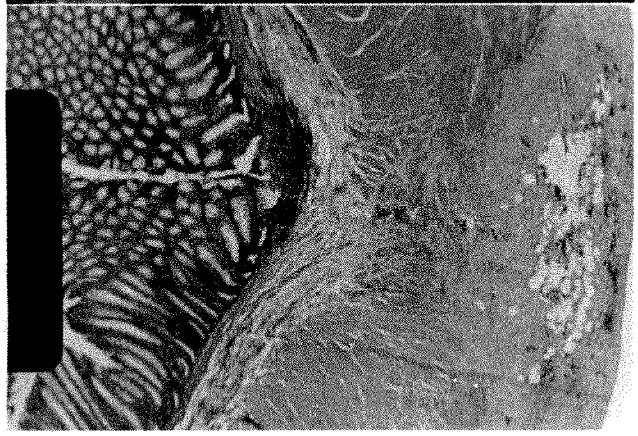
Animal Experimentation

This device was used in dogs to perform 58 colonic anastomoses, 23 times using rings of 30 mm and 35 times using the 25-mm rings. Twenty-three stapled anastomoses were performed twice using the 28 and 11 times using the 25 disposable EEA® (Autosuture, United States Surgical Corporation, Norwalk, CT); six times using the 29 and four times using the 25 ILS® (Ethicon, Sommerville, NJ). In 21 animals the new device and circular stapler were used concurrently. Condi-









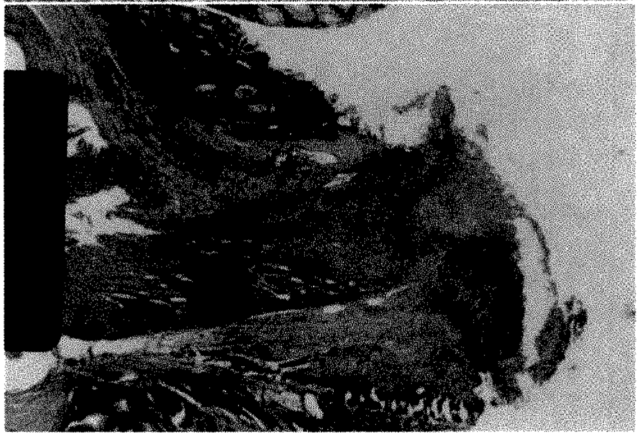


FIG. 2. (*top left*). Operative picture: the gun has been inserted transanally and the distal purse-string suture has been tied around the central shaft. The outer ring will be inserted into the proximal stump. **FIG. 3.** (*top right*). How the compression anastomosis appears after 85 days from its realization. No adhesions are evident at the site of the anastomosis. **FIG. 4.** (*middle left*). How the compression anastomosis appears at longitudinal opening of the intestinal lumen. No signs of hypertrophic scarring are present. **FIG. 5.** (*middle right*). Section of a compression anastomosis 6 days after its realization: a satisfactory alignment of the tissue layers and an initial mucosal re-epithelization are present. **FIG. 6.** (*bottom left*). Complete healing of a compression anastomosis 85 days after its realization: the process of mucosal re-epithelization is completed. **FIG. 7.** (*bottom right*). Section of a stapled anastomosis 6 days after its realization: the two mucosal surfaces are separated by an overgrowing scar tissue.

tioned dogs ranging in size from 7 to 23 kg (average 14.5 kg) were used for this study following institutional guidelines for the care and use of laboratory animals. They had a preoperative preparation of a liquid diet for 24 hours and an enema the evening before and the morning of surgery. They were operated on under general anesthesia using intravenous pentobarbital and Ethrane gas. The dogs received antibiotic prophylaxis in the form of penicillin administered intramuscularly and sterile operative technique was followed. The gun was inserted into the bowel twice through a distal colotomy and 56 times through the anus, whereas circular staplers were always introduced transanally. The bowel was prepared by devascularizing and removing all pericolonic

* Number of compression and stapled anastomoses that underwent surgical controls through relaparotomy at different postoperative time intervals.

fat within approximately 1.5 cm of the anastomotic ends. After each anastomosis, the devices were checked to assure that complete tissue doughnuts were dissected by the circular blades. In the colon containing both stapled and compression anastomoses, the former was always located in the proximal colon, whereas the latter was located in the distal colon or in the intraperitoneal rectum. No drainage tubes were placed nor was omentoplasty performed. After operation the dogs were given hypodermic 5% glucose 250 ml and water for 2 days after which a normal laboratory diet was resumed.

The anastomoses were evaluated as follows: (1) clinical controls—the dogs were examined daily. First bowel movements and expulsion of the rings were recorded. (2) Surgical controls—44 animals underwent relaparotomy, and the intestinal segment containing the anastomoses was resected at different postoperative days (Table 1). (3) Bursting pressure—the bursting pressure was tested on 23 compression and 14 stapled anastomoses, and on 13 sections of intact colon at different postoperative days (Table 2). The sections were: just distal to the cecum for the intact colon, midcolonic for the stapled anastomoses, and distal colonic or proximal rectal for the compression anastomoses. After the excised segments of colon were emptied of feces, one of the two ends was tied to a plastic nipple. The segment was flushed with water and collapsed while the other end was tied off. The nipple was connected to a syringe and to a pressure transducer attached to a strip chart recorder. Pressure values for tears or burst were recorded. (4) Histologic evaluation—macro- and microscopic evaluation were carried out on 19 compression and 7 stapled anastomoses at different postoperative intervals (Table 3). Hematoxylin and eosin staining was utilized. The alignment of the layers at the anastomotic site was specifically evaluated. In examination of the stapled anastomoses, the staples, when present, were gently removed to allow the specimen to be taken into thin sections.

* Number of compression and stapled anastomoses that underwent histologic controls at different postoperative time intervals.

Human Experimentation

Thirteen patients underwent large bowel compression anastomosis at the 1st Department of Surgery, Milan University, Milan, Italy. They were 10 males (age: 41–73 years, mean: 60.6 years) and three females (age: 48–60 years, mean: 52.6 years). Eight adenocarcinomas, two villous adenomas with severe dysplasia, one sigmoid diverticulitis, one megacolon with severe constipation, and one rectovaginal fistula after hysterectomy were the indications for surgery. All patients underwent mechanical colonic preparation and parenteral antibiotic prophylaxis with a cephalosporine. The gun was always introduced transanally according to the technique previously described. The larger ring sizes (30 mm OD) were used 11 times and the smaller rings (25 mm OD) were used twice. Seven anterior resections of the rectum-sigmoid (six times with extraperitoneal colorectal anastomosis), five left colonic resection with colocolonic anastomosis, and one total colectomy with intraperitoneal ileorectal anastomosis were performed. The tissue doughnuts cut by the circular blade were always inspected, and pneumatic control (air inflation of the anastomosis plunged under water) of the anastomosis was always carried out. A drain tube was always placed near the anastomosis. Two diverting colostomies were performed on the first very low anastomosis (the second patient of the series) and on the resection of the rectum for rectovaginal fistula, respectively. The first colostomy was closed 3 months after the operation, whereas the second one was removed on the 20th postoperative day. In one case the resection was enlarged to the dome of the urinary bladder and in another case to the uterus and ovaries. Nasogastric suction was maintained until bowel movements resumed, which then allowed oral feeding. The stools of the patients were always carefully inspected to find the anastomotic rings. Patients were discharged from the hospital only after the evacuation of the rings. All patients were controlled endoscopically 1, 3, 6, and 12 months after surgery; contrast enema were performed once a year according to our follow-up protocol for colorectal cancer (F.O.N.C.A.D.: Forza Operativa Nazionale per il Carcinoma dell'Apparato Digerente).

Results

Animal Experimentation

Clinical. One dog, who underwent both a compression and a stapled anastomosis, was not included in the study because of a technical error in the surgical procedure. At the time of operative inspection, the tissue ring cut by the circular blade of the compression anastomosis device was found to be incomplete. We decided not to redo the anastomosis and therefore had the only failure of the entire series. The postoperative course was normal for the other dogs. Normal bowel movements returned between the 2nd and 3rd postoperative day. The anastomotic rings were expelled between the 3rd and 6th postoperative day in all but one dog in which they were found in the stool at the 12th postoperative day.

Surgical. No leakages were found in the 44 compression and the 19 stapled anastomoses. In one case, a small paranastomotic abscess was found near the handsewn closure of the colotomy performed for the introduction of the device into the bowel. Compression anastomoses were found, in the majority of the cases, without or at most with very weak anastomotic adhesions (Fig. 3). In only two cases were significant adhesions found covering more than 270° of the anastomosis. In 12 of the 19 stapled anastomoses, no adhesions or at most very weak ones were found; they were covering more than 270° of the anastomosis in the remaining seven. In the 13 compression anastomoses controlled after more than 15 days from surgery (15–85 days, mean: 38 days), no signs of stenosis were detected.

Bursting pressure. Of the 24 compression anastomoses, one could not be evaluated because it broke at the time of removal and two were partially damaged but could be tested; they all were 3 day specimens. One of the 14 stapled anastomoses could not be evaluated because it also broke but at removal five days after operation. The results are shown in Table 2. As for compression anastomoses, colonic rupture occurred out of the anastomotic line at a pressure between 240 and 495 mmHg when the test was carried out immediately after the placement of the rings (time 0). It occurred at the anastomosis for the specimen tested on the 2nd, 3rd, and 5th day at a pressure between 72 and 210 mmHg, and at a pressure of 318 mmHg in one specimen on the 7th day. An extra-anastomotic rupture was recorded at a pressure between 200 and 500 mmHg in the two other 7 day specimens and in the 9 and 11 day specimens. In the two 3 day specimens partially damaged at removal, the anastomotic rupture occurred at a pressure of 66 and 68 mmHg, respectively. As for stapled anastomoses, colonic rupture occurred at the anastomosis for specimen at time 0 and on the 2nd, 3rd, and 5th day at a pressure between 100 and 246 mmHg; it was extra-anastomotic at a pressure between 330 and 384 mmHg for the 7 and 9 day specimens. In the removed proximal "normal" colon, a decrease in the bursting pressure values in the early postoperative time followed by an increase on the 5th day was observed.

Histologic features. Macroscopic appearance of compression anastomoses at the longitudinal opening of the bowel was always good. No signs of hypertrophic scar tissue were detected (Fig. 4). The stapled anastomoses were also good even though a circular fibrotic ring was almost always present. Microscopically, all the intestinal layers showed a good alignment on compression anastomoses. A rapid re-epithelization of the mucosa was observed. No signs of inflammation or at most only moderate signs were detected (Figs. 5 and 6). Stapled anastomoses showed a moderately good alignment of intestinal wall layers. At the anastomosis, a wide area of granulation tissue with lack of re-epithelization was constantly present. A prolonged chronic inflammation due to foreign bodies was also always observed (Fig. 7).

Human Experimentation

Canalization to gases resumed as usual between the 3rd and 5th postoperative day. Canalization to feces oc-

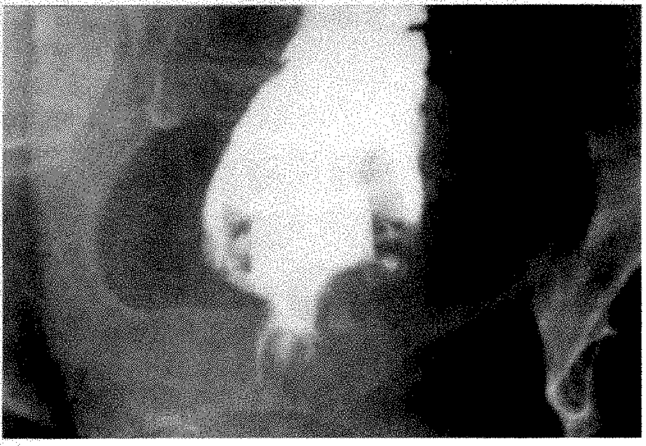

FIG. 8. Enema with liquid contrast of a low colorectal anastomosis at the 7th postoperative day. The rings are still in place and the contrast easily passes through the anastomotic apparatus.

curred between the 5th and 9th postoperative day, not affected by the presence of the rings at the anastomotic site (see Fig. 8). The rings were evacuated between the 8th and 13th postoperative day (mean: 11.2) without causing any discomfort to the patients. No significant postoperative fever was recorded. As for postoperative complications, we observed one (7.7%) subclinical leakage: it appeared in a very low colorectal anastomosis on the 7th postoperative day, revealed by the presence of fecal material in the drainage tube. No fever, peritonitis, or other general symptoms were registered. The rings were still present at the anastomotic site and the patient had regular evacuations. An enema performed on the 9th postoperative day showed the immediate drainage of the liquid contrast medium through the tube that was in contact with the colonic wall at the anastomotic site. The patient healed in 8 days by just progressively withdrawing the tube without needing a diverting colostomy. No other complications were observed. At radiologic and endoscopic long-term controls, wide anastomoses were observed without evidence of strictures (Fig. 9). The anastomotic line was often difficult to recognize even *via* videoendoscopic controls.

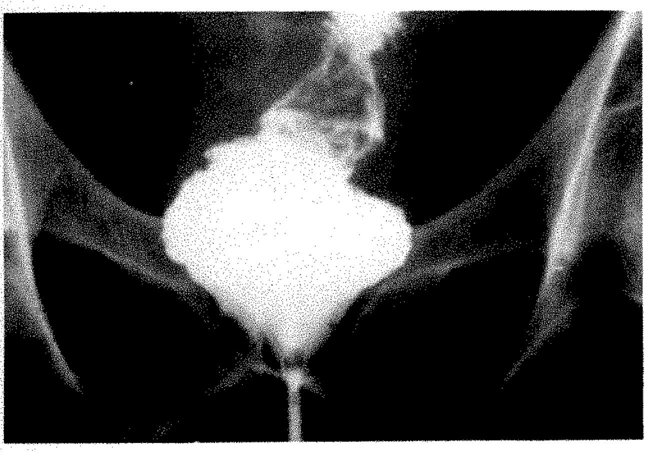

FIG. 9. Enema with liquid contrast of a low colorectal anastomosis at the 13th postoperative day. The rings have been evacuated and the anastomosis is wide.

Discussion

Anastomotic buttons, realizing a sutureless anastomosis through the compression of the edges of the intestinal stumps, have elicited a great debate in gastrointestinal surgery over the last 150 years.[1-4] In fact, even if the concept was well accepted by the majority of surgeons, the mechanical means for its realization have been considered inappropriate. Murphy's and other anastomotic buttons were mainly criticized for their narrow inner caliber and their difficult placement and assemblage that required a contaminating surgical technique. Furthermore there were no satisfactory control means for their correct positioning.

The Soviets have recently introduced a device, AKA-2, which places compression anastomotic rings. This gun has been used with good clinical results in colorectal surgery.[5,7] The rings, made of a plastic material, are held together by a series of metal pins provided with small coaxial springs. The gun is reusable and needs to be assembled and loaded at the time of surgery.

The device we developed places molded polypropylene rings, which are assembled by clinging one into each other. In the current study we used a steel reusable prototype: a completely disposable device is currently under study. The surgical technique to be followed for the execution of the anastomosis is similar to that usually used for staplers.[6] However, extraction of the gun from the anastomosis, which is a challenging maneuvre with staplers,[8,9] is automatic with this device. In fact, after cutting the bowel edges closed by the two purse-string sutures around the central shaft, the circular blade also cuts the central part of the outer ring. This, together with the thrust of the intermediate ring out of its site by means of the inner ring, realizes the automatic disengagement from the gun of the three joined rings. Therefore, the execution of the anastomosis is concurrent with the extraction of the gun.

The tissue doughnuts cut by the circular blade must be, as for staplers, carefully inspected.[10] They must be complete to ensure that the tissue ends are comprised between the rings. We observed in a dog the outcome of a technically incorrect anastomosis (the one with incomplete doughnuts that was, therefore, not included in the evaluation) and we registered the only leakage of our experimental series. Thus, we believe that this control is of the utmost importance for a successful outcome of the anastomosis.

The canalization with regular stool evacuation was not impaired by the presence of the rings. Even with smaller size rings (25 mm O.D.) at the anastomotic site, a normal evacuation of solid stool was recorded.

At reoperative controls, compression anastomoses always appeared good and just a thin pale line was often visible from outside. In the specimen containing both the anastomoses, the compression ones were always at a lower site than stapled ones, sometimes even being colorectal. No leakages, which also in animals are more frequently reported for anastomoses involving the rectum,[11] were recorded in these experimental series. Anastomotic adhesions account for a lower percentage of cases in compression than in stapled anastomoses. This is probably due to the fact that in the latter, foreign bodies, like staples, are prominent also from the serosal side.

Due to the small figures, no statistical evaluation was performed on the bursting pressure values. With the rings at the anastomotic site, tears of the intestinal wall were extra-anastomotic immediately after their placement. They were anastomotic 2 days after surgery for pressure over 70 mmHg, a value normally referred to as satisfactory.[12] On the 3rd postoperative day, in all the examined specimens, the rings could still be found inside the intestinal lumen but were already detached from the anastomosis. The bursting pressure values were still over 90 mmHg in the undamaged anastomoses. Extra-anastomotic tears 1 week after surgery at high pressure values were again recorded. Considering that pressure values in a dog's colon range between 0 and 30 mmHg, the results we achieved in our experimentation seem encouraging.

Bursting pressure was also examined on intact colon specimens. The decreasing values we found in the early postoperative stages, with subsequent rise and stabilization, have multiple interpretations. Similar results were obtained by others in rat colons.[13-16] These were explained through an early postoperative increase of the collagenase activity concurrent with a reduction in the collagen content of the colonic wall.

Histologic examination has given the most significant data. In all the compression anastomoses, the alignment of the tissue layers was satisfactory and the mucosa showed a rapid re-epithelization without formation of a circular fibrotic ring. No signs or at most only moderate signs of inflammation were present. In the stapled anastomoses we examined, as observed by others,[17] the alignment of the intestinal wall layers was moderately good. At the site of the anastomosis, a wide area of granulation tissue with marked disepithelization was constantly present and a prolonged chronic inflammation due to foreign bodies was also observed. These data indicate that compression anastomoses heal more quickly than stapled ones.

With these encouraging results in animal experimentation, we decided to begin human investigation in colorectal surgery. The patients were previously informed they would be operated on with a new device under investigation and they gave us their permission. We started with low-risk patients in order not to affect the evaluation of possible complications. After ten cases with positive results, we admitted to the study patients with increased risk of complications. In fact, the device was successfully used on a 73-year-old man with cancer infiltrating the urinary bladder (anterior resection of the rectum with bladder resection) and on a 61-year-old woman with long-standing diabetes and a cancer infiltrating the uterus and left ovary (anterior resection of the rectum with hystero-ovaryotomy).

There were two diverting colostomies. The first was performed on the second patient in our series who had a colorectal anastomosis located 5 cm above the anal verge. He had no complications and no colostomies were performed later on patients operated on for low rectal cancer. The second colostomy was done recently on a patient operated on elsewhere for a hysterectomy and who complained of a rectovaginal fistula. At time of operation, due to the highly contaminating procedure of resecting the rectum, the fistula, and the vaginal fornix, we decided to protect the anastomosis with fecal diversion. After the evacuation of the rings on the 13th postoperative day, we studied the anastomosis with a liquid contrast enema and, as it appeared satisfactory, we were able to close the colostomy on the 20th day.

The only postoperative complication observed was a subclinical leakage. It appeared on the 7th day and the hypothesis that it was caused by a decubitus of the drainage tube on the colonic wall at the anastomotic site is strongly suggestive. Furthermore, it was of little importance and the patient healed by only withdrawing the tube without needing reoperation.

Long-term controls have all confirmed the good quality of the anastomoses that, radiologically and even endoscopically, were often difficult to identify.

Conclusion

The preliminary results were have obtained in this study indicate the object of this study to be a reliable anastomotic device. Biologically, there is no doubt that a sutureless anastomosis is the ideal concept, as believed by Murphy, and to which every surgeon must aim. Mechanically, the anastomotic apparatus proved reliable and the gun, when available as completely disposable, will satisfy the need for properly functioning device.

Further experimentation can be justified to achieve statistical significance in the results. Our application in humans showed encouraging preliminary results. A wider clinical experimentation is needed to confirm what we obtained; a multicentric trial would be advisable for this purpose.

Pancreaticogastrostomy Following Pancreatoduodenectomy

PHILIPPE ICARD, M.D., and FRANÇOIS DUBOIS, M.D.

From the Department of Digestive Surgery C.M.C. de la Porte de Choisy, Paris, France

Operative death following pancreatoduodenectomy results essentially from a pancreatojejunal anastomosis leakage. Pancreaticogastrostomy has been used infrequently. Seventeen patients (12 with malignant tumors and 5 with chronic pancreatitis) have undergone pancreaticogastrostomy following pancreatoduodenectomy. There was no operative mortality rate and no pancreaticogastrostomy leakage. Our data agree with data concerning pancreaticogastrostomy published in literature; cumulative mortality rate including our results is 4.5% (6 out of 134 patients) with only one transient benign pancreatic fistula reported. Many advantages offered by this method can explain these positive results including trypsine neutralization by gastric acidity and the possibility of nasogastric aspiration on contact with the anastomosis. Furthermore, permeability of the pancreatic duct can be easily verified by endoscopic examination. However, external pancreatic insufficiency does not seem to occur in long-term follow-up. These results suggest that this simple and safe method merits a more widespread application.

THE MORTALITY RATE following pancreatoduodenectomy in most centers is approximately 7–20%.[1-5] In approximately 50% of the cases, the mortality rate seems to be related to a pancreaticojejunal anastomosis leakage.[6,7] Although a wide variety of methods of reconstruction after Whipple resection have been described, a method for preventing this leakage is still awaiting widespread recognition. Waught and Clagett[8] in 1944 performed the first human pancreaticogastrostomy. Despite the low mortality and morbidity rates encountered after pancreaticogastrostomy, this method has been used only occasionally.[9-17] Our early clinical results in 17 patients who have undergone a pancreaticogastrostomy are reported here.

Methods

Technical Aspects

After removal of the head of the pancreas with the entire duodenum and the distal part of the stomach, the transected surface of the remaining pancreas, proven free of tumor, was freed from retroperitoneal attachment for 1–2 cm.

A corresponding transverse opening of about 3 cm was made on the posterior gastric wall, and the anastomosis was performed with an interrupted row of 3/0 polyglycolic acid sutures. Each stitch was passed through the pancreas, through the main duct, especially when the duct was dilated, and through the seromuscular layer of the stomach (Fig. 1). The posterior row of sutures was tied from the inside and the anterior row from the outside. Biliary anastomosis was then performed, followed by gastrojejunal anastomosis approximatively 30/40 cm distal to it (Fig. 2). Cholecystectomy was performed in all patients but not vagotomy. Drainage was placed to the right and posterior of the pancreaticogastrostomy. Nasogastric aspiration was left in place until the return of intestinal activity.

Patients

From September 1981 to December 1986, 17 patients (average age: 60 years, ranging from 34–81 years) underwent pancreatoduodenectomy with pancreaticogastrostomy. Twelve patients had malignant tumors (7 pancreatic adenocarcinoma, 3 duodenum cancer, 1 ampullary cancer, and 1 sarcoma). Five patients had chronic pancreatitis on histologic examination.

Submitted for publication: August 14, 1987.

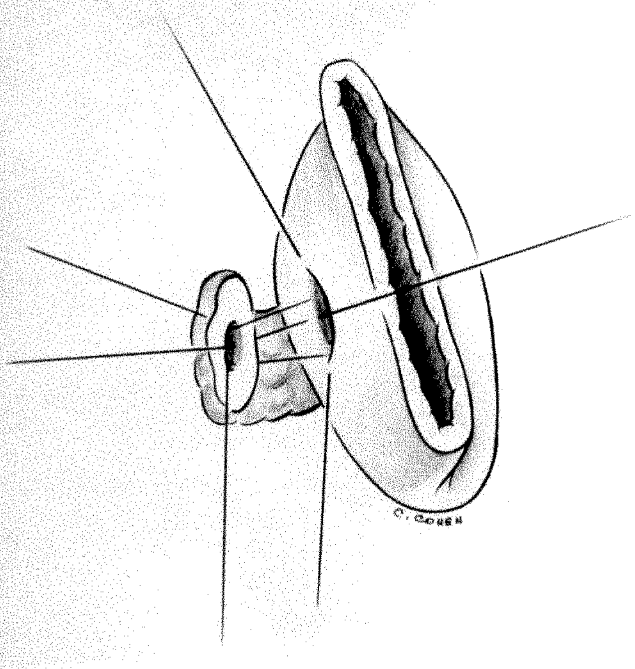

FIG. 1. Row of interrupted 3/0 sutures between the anterior surface of the pancreas and the posterior wall of the stomach.

Results

The major results were as follows: (1) there was no operative mortality rate; (2) no pancreatogastric anastomosis leakage occurred; and (3), postoperative complications occurred in two patients. One patient had peritoneal bleeding due to a breakdown of hemostasis on a collateral of the mesenteric superior vein, which was controlled by prompt reoperation. Another patient had continuous gastrointestinal bleeding. Endoscopic examination and reoperation with gastrostomy failed to reveal the origin of this bleeding, which stopped spontaneously.

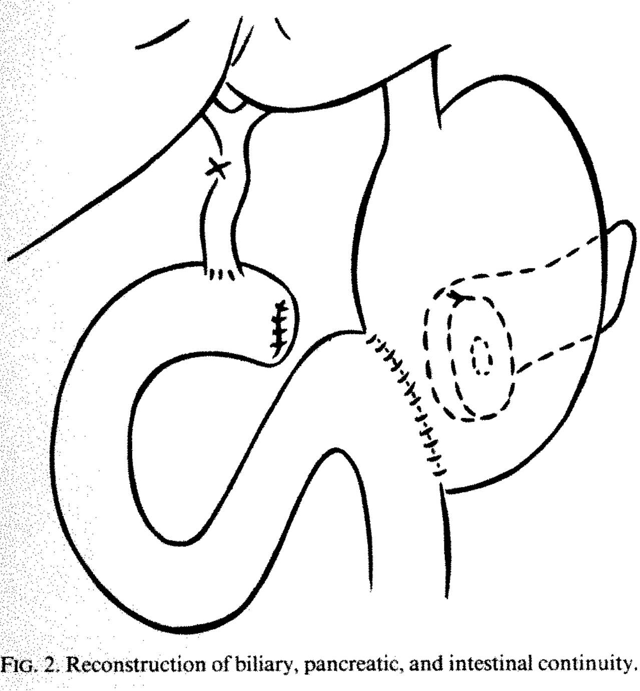

FIG. 2. Reconstruction of biliary, pancreatic, and intestinal continuity.

Thus, morbidity rates in relation to the pancreaticogastrostomy may perhaps be attributed to this gastrointestinal bleeding. The average postoperative hospital stay was 15 ± 3 days. Periodic clinical evaluations in all patients suggest the permeability of the pancreatic duct because none of the patients presented with symptoms of pancreatic insufficiency. One patient (chronic pancreatitis) had two recurrent anastomotic ulcers (after 12 and 20 months, respectively), which necessitated two successive degastrogastrostomies and truncal vagotomies (the latter were performed by left thoracotomy). Three out of 11 patients with malignant tumors died 13, 24, and 50 months after the operation, respectively, and postmortem examination confirmed the permeability of the pancreatic duct.

Discussion

On the basis of experimental studies on dogs carried out by Tripodi and Sherwin in 1934[18] and then by Person and Glenn in 1939,[19] which showed evidence of long-term pancreatic secretion after pancreaticogastrostomy, Waugh and Clagett in 1944[8] performed the first human pancreaticogastrostomy. This technique, though rarely used, was reintroduced by Mackie et al.[17] in 1975 and by Reding[20] in 1978.

Our results (no mortality and low morbidity rates without pancreaticogastrostomy leakage) are consistent with data concerning this method of reconstruction published in the literature: cumulative mortality is 4.5% (6 out of 134 patients, including our patients) with only one pancreatic leakage, mentioned by Mackie (Table 1). This single case of pancreatic fistula disappeared after prolonged use of nasogastric aspiration. The main complication appears to be pancreatic anastomosis bleeding in the stomach (4 cases out of 136 patients); thus, we recommend careful hemostasis of the pancreaticogastric anastomosis.

Pancreaticogastrostomy presents the following advantages:

1. It is a simple method of reconstruction because the pancreas lies in natural apposition to the posterior wall of the stomach, and so the anastomosis is easy to accomplish technically without tension.
2. The very low incidence of pancreatitis and pancreatic fistula is probably a consequence of trypsine neutralization by gastric acidity.

* Pylorus preservation.

Other probable contributing factors are the possibility of nasogastric aspiration on contact with the anastomosis; and the absence of a long jejunal loop where pancreatic and biliary secretions can accumulate, increasing intraluminal pressure and loop weight. Furthermore, the significant distance between pancreatic and biliary anastomosis prevents, in the event of leakage of one of these anastomosis, deleterious effects on the other.

Telescoping the pancreatic stump into the posterior wall of the stomach[17] or performing mucosa-to-mucosa anastomosis[21] have been proposed. Nevertheless, in our opinion, none of these technical modifications seems necessary. Radiologic and endoscopic access to pancreaticogastrostomy is simple, allowing long-term evaluation of the permeability of the anastomosis and of the amount of pancreatic enzymes. Thus, Millbourn[15] successfully reperformed reanastomosis because of an obliterated duct discovered 2 years and 3 months after initial pancreaticogastrostomy. Current progress in endoscopic surgery would probably prevent the necessity of such a reoperation.

To prevent anastomotic peptic ulceration and weight loss, pylorus preservation has been recommended primarily in chronic pancreatitis.[22,23] This pylorus preservation can be performed with pancreaticogastrostomy, as Flautner et al.[24] have reported. The almost unanimously reported positive results after pancreaticogastrostomy are comparable with the best results reported after pancreatojejunal anastomosis in most recent series.[4,25–29]

In conclusion, this method of reconstruction merits widespread utilization due to its simplicity and safety.

THE BILLINGS CLINIC

Certified Cardiopulmonary Perfusionist

Progressive medical center in the Northwest area is seeking a certified Cardiovascular Perfusionist. Qualifications: Applicant must be certified or eligible for certification as a Perfusionist; licensure as a registered nurse is helpful but not required; demonstrated ability to work effectively with cardiovascular team. Salary commensurate with experience, excellent benefits.

Forward resume to:

Personnel Manager
The Billings Clinic
P.O. Box 35100
Billings, MT 59107-5100.

Victoria Ann-Lewis moves so gracefully on stage the audience doesn't even know she has polio.

VICTORIA ANN-LEWIS/ARTIST IN RESIDENCE AT THE MARK TAPER FORUM IN LOS ANGELES.

Believe in them.
Break the barriers.

PRESIDENT'S COMMITTEE ON EMPLOYMENT OF THE HANDICAPPED,
WASHINGTON D.C. 20210

PRODUCED BY THE SCHOOL OF VISUAL ARTS PRESS, LTD

Pediatric Urologist

Interesting pathology, state-of-the-art equipment and teaching/research opportunities are yours at the Geisinger Clinic. Bring your own unique highly specialized skills to this elite team, where 380 staff physicians and more than 200 physicians in residency are providing the best in health care to 2.7 million people.

The **Urology Department** offers you:
- excellent equipment from YAG and Argon lasers to the state's second lithotripter;
- more than 15,000 clinic visits and 2600 surgical cases per year running the full gamut of neonatal and pediatric pathology;
- highly trained staff of 4 Board Certified physicians, 5 residents and 1 Physician Assistant.

To be considered for this opportunity, you must have subspecialty preparation through a Fellowship and have exceptional academic credentials and surgical skills.

In exchange, you receive compensation based on credentials/experience, liberal benefits and the chance to enjoy it all in a beautiful, family oriented setting.

Inquire in confidence immediately by sending your CV or calling:

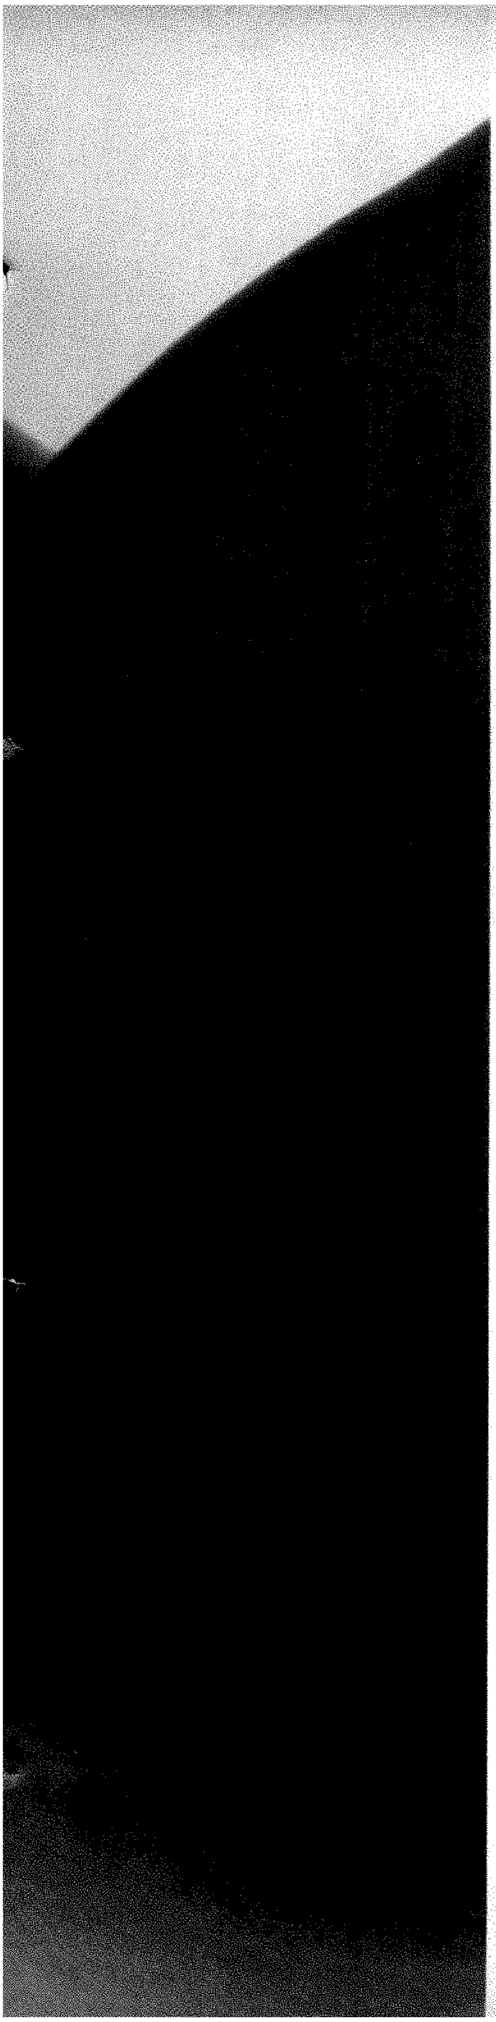
CHIEF OF DIVISION OF PLASTIC SURGERY

The UCLA School of Medicine is searching for a Chief of the Division of Plastic Surgery. Plastic Surgery is one of nine Divisions in the Department of Surgery. Candidates for this position will be surgeons with proven contributions to research, with strong commitments to education and training, and recognition as an excellent surgeon and clinician. Recommendations and inquiries should be directed to

Donald G. Mulder, M.D., Acting Chairman
Department of Surgery
UCLA Center for the Health Sciences
Los Angeles, Ca. 90024

UCLA is an affirmative action employer.



MEDICAL TECHNOLOGY THAT CONQUERS WITHOUT INVADING.

The human body. As a doctor, all your efforts aim at helping it, healing it, curing it.

With as little risk and as little pain as possible.

At Dornier, we share those goals. Our first contribution to the medical field, the extracorporeal shock wave lithotripter, revolutionized the treatment of kidney stones. In place of surgery, it substituted a procedure that involves no invasion of the body, no lengthy recuperation, and much less risk.

That is why the medical profession embraced our concept eagerly. And today, over 300,000 successful kidney stone treatments have already been performed.

But kidney stone lithotripsy is only the beginning. Merely the first step in a vision that extends far beyond kidney stone treatment alone.

Dornier, relying on its broad research base, is now pursuing the application of extracorporeal lithotripsy for gallstones. And other medical conditions.

We will continue to build on the 20 years of experience we have in the clinical advancement of lithotripsy. Twenty years of experience all aimed at a single goal.

Not simply conquering the body's illnesses, but conquering them the best way of all.

Without invasion.

For more information, contact Dornier Medical Systems, 824 Livingston Court, Marietta, GA 30067. Or 1-800-DORNIER.

DORNIER

DORNIER MEDICAL SYSTEMS

Striving for excellence . . .
Committed to a better future.

Michael E. DeBakey
International Surgical Society
VII Biennial Meeting
20, 21, 22, 23 April 1988
Houston, Texas

Registration:
Program fee is $200. Physicians in residency training, medical students, and registered nurses will be admitted without charge.

COMPREHENSIVE AUTOLOGOUS TRANSFUSION CONFERENCE

APRIL 18 – 21, 1988

Presented by Haemonetics® Corporation, Norton Hospital, Kosair Children's Hospital, in cooperation with the University of Louisville School of Medicine.

This program is designed to offer an indepth examination of Autologous transfusion and its' relationship with the various medical disciplines. The topics will include:

- coagulation and hemostasis
- clinical immunology and hemolysis
- quality control
- equipment operation

CEU's will be offered. For further information and to receive a brochure contact:

BURN FELLOWSHIP

The New York Hospital-Cornell Medical Center Burn Center is a modern burn treatment facility with 24 intensive care beds and annual admissions of 850 in-patients and 3,000 out-patients. During the year's experience, the Fellow will be responsible for the surgical critical care of all burned patients, for house officer education, and for participation in original and on-going clinical research protocols. The Burn Center is the recipient of an NIH Burn Research Center Grant and supports comprehensive laboratories with state-of-the-art instrumentation and active investigators in the fields of wound healing, immunology, metabolism, nutrition, and cardiopulmonary response to injury. An additional year in the laboratory may be elected by the Fellow. Candidates preferably should be Board eligible in General Surgery, but we will strongly consider academically oriented senior surgical residents from university programs incorporating the Fellowship as part of their training programs. Send inquiries to:

ZANTAC® Injection **BRIEF SUMMARY**
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Carcinogenesis, Mutagenesis, Impairment of Fertility: There was no indication of tumorigenic or carcinogenic effects in lifespan studies in mice and rats at oral doses up to 2,000 mg/kg/day.

Ranitidine was not mutagenic in standard bacterial tests *(Salmonella, E coli)* for mutagenicity at concentrations up to the maximum recommended for these assays.

In a dominant lethal assay, a single oral dose of 1,000 mg/kg to male rats was without effect on the outcome of two matings per week for the next nine weeks.
Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
Use in Elderly Patients: Ulcer healing rates in elderly patients (65 to 82 years of age) treated with oral ZANTAC were no different from those in younger age groups. The incidence rates for adverse events and laboratory abnormalities were also not different from those seen in other age groups.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC®.

The following have been reported as events in clinical trials or in the routine management of patients treated with oral ZANTAC. The relationship to ZANTAC therapy has been unclear in many cases. Headache, sometimes severe, seems to be related to ZANTAC administration.
Central Nervous System: Rarely, malaise, dizziness, somnolence, insomnia, and vertigo. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.
Cardiovascular: Rare reports of tachycardia, bradycardia, and premature ventricular beats.
Gastrointestinal: Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain.
Hepatic: In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid IV for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.
Musculoskeletal: Rare reports of arthralgias.
Hematologic: Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.
Endocrine: Controlled studies in animals and man have shown no stimulation of any pituitary hormone by ZANTAC and no antiandrogenic activity, and cimetidine-induced gynecomastia and impotence in hypersecretory patients have resolved when ZANTAC has been substituted. However, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.
Integumentary: Rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia.
Other: Rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
NDC 0173-0362-38 2-ml single-dose vials (Tray of 10)
NDC 0173-0363-39 10-ml multi-dose vials (Singles)
NDC 0173-0362-01 2-ml single-dose, prefilled, disposable cartridge-needle units (Tray of 10)
NDC 0173-0362-00 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC® Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

Pancreatitis in Childhood

Experience with 49 Patients

DANIEL W. ZIEGLER, M.D., JULIE A. LONG, M.D., ARVIN I. PHILIPPART, M.D., and MICHAEL D. KLEIN, M.D.

Pancreatitis in children is not common but can be associated with severe morbidity rates. We have treated 49 children with pancreatitis over the past 12 years ranging in age from 1 month to 18 years. One third of the patients had biliary tract disease as an etiology, with nearly half of these being related to underlying hematologic disease, usually sickle cell anemia. Another third of the pancreatitis was due to trauma, and one third of these were related to child abuse. Other etologies were systemic disease (6 patients), congenital anomalies (8 patients), and idiopathic (3 cases). Eighty-two per cent of the patients presented with abdominal pain, but four children, all less than 4 years old, presented with an abdominal mass. Twenty-nine patients required 33 operations for pancreatitis. Fifteen of the 16 patients with biliary tract disease and all patients with congenital anomalies required operation. Six of the 16 patients with trauma required operation and none of those with systemic disease. As in adults ultrasonographic examination and CT scan are most important in the diagnosis; medical treatment consists of intravenous (I.V.) fluids, nasogastric suction, and total parenteral nutrition (TPN), and risk factors can help predict the severity of the disease while amylase alone is not related to severity. Different from adults, in children an etiology can usually be determined. The common etiologies, biliary tract disease, trauma, and congenital anomalies frequently require operation.

PANCREATITIS in children is not common but can be associated with severe morbidity rates. Mortality rates range from 0–78%.[1-5] In most series, the etiology of pancreatitis in childhood is either trauma or unknown.[1,2,4] We treated 49 children over a 12-year period at a single institution. Biliary tract disease emerged as a frequent cause of pancreatitis, and a diligent search for the cause of pancreatitis was successful in 94% of the cases.

From the Department of Surgery, Wayne State University School of Medicine, and the Department of Surgery, Children's Hospital of Michigan, Detroit, Michigan

Materials and Methods

The records of 49 patients with the diagnosis of pancreatitis hospitalized at the Children's Hospital of Michigan between 1974 and 1986 were reviewed. The criteria for diagnosis were amylase measurements in 27 patients (serum amylase greater than 200 IU/dL/24 h or urine amylase greater than 300 IU/24 h) and intraoperative pathology consistent with pancreatitis in 22 patients.

Results

These 49 patients ranged in age from 1 month to 18 years and included 27 males and 22 females (Table 1). Trauma accounted for 33% of the cases of pancreatitis. Nonmotorized vehicles were associated with five cases whereas motor vehicles contributed to three cases. In five cases (10% of the series) child abuse was the etiology. The average age of these children was younger than any other group (including congenital anomalies) presenting at 27 months. Other blunt trauma caused three cases. No case of pancreatitis was associated with penetrating trauma in this series.

Sixteen patients had pancreatitis associated with biliary tract disease. The most common etiology was sickle cell anemia (six patients). All of the patients with sickle cell disease had multiple admissions for abdominal pain with some episodes not typical for sickle cell crisis. Eight patients without sickle cell disease also had cholelithiasis. Three had no predisposing factors for gallstones and five did. One had morbid obesity, 1 was using corticosteroids for a kidney transplant, 1 had cryptogenic cirrhosis, 1 had G-6-PD deficiency, and 1 had hemolytic-ure-

Submitted for publication: September 15, 1987.

TABLE 1. *Etiology, Age, and Sex Distribution of Children with Pancreatitis*

Etiology	No. of Patients (%)	Mean Age (yr) (Range)	Male:Female Ratio
Biliary tract (ALL)	16 (33)	12.3 (3.7–18)	7:9
Related to hematologic disease	7 (14)	12 (9–17)	4:3
Trauma	16 (33)	5.7 (0.3–13.8)	3:1
Systemic disease	6 (12)	10.8 (4–15)	5:1
Congenital anomalies	8 (16)	5.9 (0.08–14)	1:3
Idiopathic	3 (6)	14.3 (12–16)	3:0
Total	49	10.6 (0.08–18)	27:22

mic syndrome. Two patients had biliary tract disease without sickle cell anemia or cholelithiasis. One had already had a cholecystectomy at another hospital, and the other had a dilated common hepatic duct and common bile duct on endoscopic retrograde cannulation of the pancreatic duct (ERCP) without stones or stricture raising the question of prior passage of a gallstone.

Of the six patients with an underlying systemic disease, one had mumps encephalitis and five had diabetes mellitus (including one patient who also had cystic fibrosis). The congenital anomalies included four anomalies of the biliary and pancreatic ducts, a gastric duplication cyst, two choledochal cysts, and a pancreatic cystadenoma associated with cytomegalovirus infection. The four ductal anomalies included a pancreas divisum, pancreatic ductal cyst, atresia of the duct of Wirsung with stenosis of the duct of Santorini and separate common bile duct entrance, and a duodenal diverticulum associated with dilated bile ducts and an ectopic sphincter of Oddi.

Three patients remained without an apparent etiology for their pancreatitis. In two of these cases the clinical course was mild, and in one it was protracted. Forty of 49 patients (82%) presented with abdominal pain. The pain was described as generalized in six, epigastric in 11, and right upper quadrant in 16. One had radiation of pain to the back. Twenty-six patients presented with vomiting and three had vomiting with no abdominal pain. Four children, all less than 4 years old, presented with an abdominal mass without pain. Additional findings were fever in 6 patients, abdominal distention in 18 patients, jaundice in 3 patients, and pleural effusion in 1 patient.

TABLE 2. *Relationship of Age to Presenting Signs and Symptoms*

	Age (yr)			
	0–5 (N = 15)	5–10 (N = 13)	10–18 (N = 21)	Total
Pain	10 (67)	11 (85)	19 (90)	40 (82)
Vomiting	8 (53)	7 (54)	11 (52)	26 (53)
Mass	5 (33)	0	3 (15)	8 (16)
Fever	2 (14)	2 (15)	1 (5)	5 (10)
Distention	9 (64)	3 (23)	6 (30)	18 (37)
Other	0	7 (54)	2 (10)	9 (18)

Percentages are given in parentheses.

The relationship of age to signs and symptoms is presented in Table 2. Younger patients often presented without pain and were more likely to have abdominal distension. Forty-two patients had plain films of the abdomen and 23 (55%) had abnormal findings. Five patients had calcifications in the area of the pancreas and 14 had a pattern of ileus. The other three revealed evidence of a mass effect in the upper abdomen. Twenty-four patients had an upper gastrointestinal (UGI) series. This was abnormal in ten, with three patients demonstrating displacement of the duodenum.

Thirty-four patients had ultrasonography and 12 had a CT scan. The ultrasonographic examination demonstrated a pancreatic mass in 10 and an enlarged pancreas in 13. In nine patients, the pancreas could not be specifically identified. The CT scan demonstrated a pancreatic mass in 6, an enlarged pancreas in 9, and a normal pancreas in 2. There was no age correlation with ability to image the pancreas by ultrasound.

Fifteen of the 49 patients had a pancreatic mass detected by physical examination or some imaging technique. Eight of these were pseudocysts, 1 was a duplication cyst, 4 were congenital cysts, and 2 were pancreatic abscesses. Thirteen of 15 patients with a mass had an ultrasonographic examination. The ultrasonographic examination demonstrated the mass in ten patients. In one patient with a duplication cyst, the ultrasound did not demonstrate the mass but it was demonstrated on CT scan.

We used ERCP in three of our patients to evaluate recurrent pancreatitis. The ERCP established a diagnosis of pancreas divisum in one patient. One patient had a fibrosed pancreatic duct, and the third was normal. In no case did the ERCP cause an exacerbation of pancreatitis.

We retrospectively graded the severity of pancreatitis in this series using Imrie's modification of Ranson and Pasternack's criteria.[6,7] The ten factors utilized and the frequency of their occurrence are listed in Table 3. In contrast to Ranson's criteria this study excluded age at admission, history of previous episodes, high base deficit, and estimated fluid sequestration because of characteristics unique to a pediatric population or lack of data. In Table 4 the number of positive factors in a patient is related to the amylase level and complications.

TABLE 3. *Risk Factors in Children with Pancreatitis*

Factor	No. of Patients
White count ≥16,000/mm^3	14
Calcium ≤8 mEq/dL	3
Fasting blood sugar ≥200 mg/dL	5
LDH ≥350 IU	3
SGOT ≥250 IU	1
PaO$_2$ ≤60 mmHg	4
Fall in hematocrit of more than 10% in 24 h	2
Rise in BUN more than 5 mg/dL in 24 h	0

TABLE 4. *Correlation of Risk Factors and Amylase with Complications in Children with Pancreatitis*

No. of Factors	No. of Patients	Average Amylase Level	Complications	%
0	25	1038	5 Recurrences	20
			2 Pseudocysts	8
1	19	1229	2 Recurrences	10
			4 Pseudocysts	21
2	1	913	0 Recurrences	0
			2 Pseudocysts	0
3	1	918	0 Recurrences	0
			1 Mortality	100
4	3	2972	3 Recurrences	100
			1 Pseudocyst	33
			2 Pancreatic abscesses	67

Fourteen patients were treated with I.V. fluids and no oral intake. Six of these patients required an operation during their hospitalization. Seventeen patients were initially treated with I.V. fluids and nasogastric suction. Eleven required surgery. Eighteen patients were treated with I.V. fluids, nasogastric suction, and hyperalimentation. Twelve required operations.

A total of 29 patients (59%) required operation (Table 5), and four required reoperation for complications or continued pancreatitis. Fifteen of 16 patients with biliary tract disease had operative procedures. Each of these patients had cholecystectomy, 12 with cholangiography including four with common bile duct explorations. The majority of these procedures were performed following typical episodes of gallstone pancreatitis. Six patients with sickle cell anemia were treated medically for the acute attack, and five underwent exchange transfusion followed by cholecystectomy with no postoperative recurrence. One patient developed recurrent pancreatitis following cholecystectomy, and subsequent evaluation failed to reveal an etiology. There was not one mortality in the surgically treated group.

Five of the operated patients developed recurrences. Three patients required more extensive procedures: 1 cholecystectomy with duodenotomy and Roux-en-Y choledochojejunostomy, 1 cholecystectomy with external drainage of a pseudocyst, and 1 cholecystectomy with pancreatic cystogastrostomy. Six of 16 patients with traumatic pancreatitis required operation. One patient initially operated on at an outside hospital required reoperation to drain an abscess. The other five patients all had drainage of fluid collections: 2 laparotomies with drainage of the lesser sac, 1 cystogastrostomy, 1 Roux-en-Y pancreatic cystojejunostomy, and 1 external drainage of pseudocyst with jejunal resection. One patient with percutaneous drainage of the pseudocyst was spared laparotomy but required 2 months of further hospitalization.

All eight patients with congential anomalies had operative procedures. One patient with an ectopic sphincter was treated with cholecystectomy and transduodenal sphincterotomy. A case of gastric duplication underwent distal pancreatectomy, resection of jejunum, and gastric duplication. An infant with a cystadenoma and cytomegalovirus infection had excision of cystadenoma. A patient with pancreatic cyst was treated with resection of the tail of the pancreas. A patient with stenosis of the duct of Santorini and atresia of the duct of Wirsung delineated by intraoperative pancreatogram had cholecystectomy with common bile duct exploration and transduodenal sphincteroplasty. One case of pancreas divisum was treated with cholecystectomy, pancreatogram, and Santorini sphincteroplasty. This patient required a Roux-en-Y pancreatic cystojejunostomy revision. Two choledochal cysts were treated by resection and Roux-en-Y choledochojejunostomy.

None of the six patients with systemic disease and pancreatitis required operation. One of three patients with idiopathic pancreatitis underwent exploratory laparotomy and external drainage of a pancreatic pseudocyst. Morbidity other than recurrence occurred in ten patients. Six required ventilatory support. One patient had a cardiac arrest from hypercalcemia. One patient

TABLE 5. *Operative Treatment of Pancreatitis in Children*

Etiology	No. of Patients	No. Operated	Recurrence
Biliary tract	16	14	—
Hematologic disease	7	6	0
Other	9	8	3
Trauma	16	6	1
Congenital anomalies	8	8	1
Systemic disease	6	0	0
Idiopathic	3	0	0
Total	49	29	5 (18)

had intractable seizures requiring phenobarbital coma. One patient with sickle cell anemia developed respiratory distress after an exchange transfusion. One patient had respiratory failure with sepsis. Two patients with severe pancreatitis presented with shock and respiratory failure.

Discussion

Although pancreatitis is uncommon in childhood, it should be suspected in children with abdominal complaints. Not all children with pancreatitis present with abdominal pain. In this series seven patients (16%) presented with vomiting and four (9%) presented with an abdominal mass. Other patients without significant pain presented with fever, abdominal distention, jaundice, pleural effusion, and Grey Turner's sign.

Ultrasound is very useful in the diagnosis of pancreatitis in childhood. If a diagnosis can be made with ultrasound alone, one can avoid the more expensive CT with its higher radiation. All the pseudocysts in our patients were detected by ultrasound. The usefulness of the ultrasound suffers because it cannot always visualize the pancreas. The pancreas was not visualized in 25% of our examinations. Despite common wisdom that children have less retroperitoneal fat and therefore their pancreas is difficult to visualize, the CT scan was able to visualize the pancreas in all our patients studied.[8] While ERCP was used infrequently in this series, we agree with O'Neill that it is a major tool for evaluating chronic pancreatitis and planning ductal reconstruction.[9]

The presenting age of the patient can point to the etiology of pancreatitis. While trauma is a frequent cause of pancreatitis at any age, it was the most common etiology in the youngest patients in this series. In all patients under 4 years of age, pancreatitis was caused by congenital anomalies or trauma. No history of trauma may be given in an abused infant presenting with abdominal symptoms.[10] Child abuse was responsible for a significant proportion of the cases (10%) with an average age of 27 months. Our approach, therefore, is to aggressively search for congenital anomalies and exclude child abuse in this age group.

Risk factors did help predict who would develop complications. As in adults, elevated amylase alone is not an independent risk factor for predicting severity of pancreatitis. Of 45 patients with zero to two risk factors, 6 (13%) developed a pseudocyst and 7 (16%) developed recurrent pancreatitis. Of the four patients with three or four risk factors, 1 (25%) developed pseudocyst, 2 developed abscesses (50%) and 3 (75%) developed recurrent pancreatitis. Most of the complications and the only mortality occurred in the group with three or four risk factors.

The initial treatment of pancreatitis in children includes I.V. fluids and nasogastric suction. Antibiotics are used only when there is evidence of infection. Patients with two or more risk factors warrant closer observation. Thirty per cent of our patients were successfully treated with either I.V. fluids alone or I.V. fluids and nasogastric suction. In general, enteral feeding can be started once abdominal pain has subsided and the amylase is returning to normal.

Two pediatric series with a 10–12% overall incidence of pseudocyst had a 30% incidence of traumatic pancreatitis.[1,11] Pseudocysts occurred in 17% of our cases but in 38% of our cases of traumatic pancreatitis. About 20% of pancreatic pseudocysts can be expected to resolve spontaneously.[12] Three of our patients (37%) had spontaneous resolution of the pseudocyst. While percutaneous drainage of a pseudocyst appeared to prolong the course of one of our patients, it is an option allowing stabilization of a septic patient prior to definitive surgery.

In three of our patients, steroids may have played a role in the development of pancreatitis. All of these patients had a prolonged hospitalization with complications of sepsis, respiratory, and renal failure. Although steroids have not been directly implicated in causing pancreatitis, the mortality rate in steroid-associated pancreatitis is reported to be about 50% with nonlethal underlying disease.[13,14] Close monitoring and early treatment is certainly warranted in patients administered steroids suspected of having pancreatitis.

Thirty-three per cent of our patients had pancreatitis secondary to acquired biliary tract disease. Blumenstock et al., in reviewing 36 cases of pancreatitis, cited biliary tract disease as an infrequent cause. Others report biliary tract disease as a cause in 0–24% of cases.[1-5,16] The higher incidence in this series is partially explained by the incidence of sickle cell anemia. Eight patients, however, had biliary tract disease causing pancreatitis without associated hematologic abnormalities. Two of the 14 patients (14%) with gallstone pancreatitis developed a recurrence before elective surgery was done. While this is lower than the 37% rate reported for adults, to prevent recurrences, we now recommend cholecystectomy during the initial hospitalization for gallstone pancreatitis.[17,18]

This large series of patients with pancreatitis from a single children's hospital emphasizes the similarities and differences of pancreatitis in children and adults. Aggressive diagnostic evaluation reveals a cause in 94% of cases. While it is unusual for patients with systemic disease and unknown etiology to require operative therapy, it is common for patients with traumatic pancreatitis and biliary tract disease to require operation. Operative therapy is necessary for congenital anomalies to avoid recurrent disease. The risk factors for severity of disease applied to adult populations are also useful in predicting morbidity and mortality rates in pediatric populations. The low mortality rate in this series may be due to early diagnosis and surgical intervention.

Surgical Oncology Research

A Disappointing Status Report

FREDERICK P. AVIS, M.D.,* SUSAN ELLENBERG, PH.D.,† MICHAEL A. FRIEDMAN, M.D.‡

From the Surgery Branch, National Cancer Institute, Biometric Research Branch, Division of Cancer Treatment, National Cancer Institute,† Clinical Investigations Branch, Clinical Therapy Evaluation Program, Division of Cancer Treatment, National Cancer Institute,‡ National Institutes of Health, Bethesda, Maryland*

The purpose of this paper is to evaluate certain aspects of the present status of surgical oncology research. We have attempted to define the magnitude of the problem, characterize features unique to the surgical community, and formulate potential solutions. Demographic data concerning grant applications submitted to and funded by the National Cancer Institute (NCI) over the time period from 1980 to 1985 were analyzed. Departments of surgery submitted and were awarded substantially fewer grants over the study period than departments of medicine. Additionally, the number of applications submitted from departments of medicine increased during this time period while those from departments of surgery declined. This record is particularly worrisome because it occurred during a period of time of unprecedented scientific and educational opportunities and support mechanisms provided by the NCI. Further conclusions and potential solutions are discussed in this paper.

THE NATIONAL CANCER INSTITUTE (NCI) is committed to supporting the broadest possible participation in the national research effort to elucidate the biology of and identify superior therapy for malignant diseases. In this regard, the surgical community has been actively encouraged to pursue both basic and clinical research questions. Such encouragement is a natural extension of the historically important role of surgeons as cancer investigators as well as their central role in cancer management. Consequently, over the past 8 years the Division of Cancer Treatment of the NCI has sponsored 20 separate initiatives targeted to fostering more and better surgical oncology research.

However, despite the major involvement of surgeons in the care of cancer patients, concerns of insufficient access to research support have been voiced by a variety of individual surgical investigators. Frustrated by a perceived inability to successfully compete for NCI grant support, some surgical oncologists have criticized aspects of the current NCI peer-review mechanisms of awarding grants. Because of these serious concerns, we have undertaken a study to define the magnitude of the problem, characterize features unique to the surgical community, and formulate potential solutions.

Methods

Demographic data concerning grant applications submitted and funded from a recent time period have been analyzed. This information was provided by the Division of Research Grants of the National Institutes of Health (NIH). The data were restricted to applications submitted from various clinical departments of medical schools because the Division of Research Grants' system of data collection provides information by departments only for medical schools in the United States. Therefore, other institutions such as free-standing cancer centers and non-medical school research institutes could not be considered in this paper.

Data were collected from the years 1980–1985 in order to focus on recent trends. Grant submissions were designated according to the medical school department appointment of the principal investigator. The specialty departments evaluated were: medicine, obstetrics and gynecology, radiology, pediatrics, and surgery. There is an *other* category, which includes all of the clinical departments not specifically listed above. These are listed in Table 1. Two surgical subspecialties, which had their own department codes, otorhinolaryngology and orthopedic surgery, were included with surgery. It is possible

that some grant applications were submitted by surgeons through nonsurgical departments; however, we had no way of reliably identifying such submissions. With this data base, we were able to determine numbers of applications submitted, numbers recommended for award, numbers of grants actually awarded, and the success rates (defined as the number of grants awarded divided by number of applications submitted). Comparisons of success rates by department were performed for individual years and for the entire time interval considered using a chi square test corrected for continuity. No attempt was made to differentiate between the types of grants submitted; *e.g.*, RO1, PO1, KO8, *etc.* Likewise, we did not distinguish as to whether the principal investigator held an M.D., Ph.D., or M.D.-Ph.D. degree, nor did we perform analyses based upon the study section to which an application was submitted. These data are available and will form the basis of a subsequent analysis. To place the information concerning the NCI in proper perspective, these data were compared to similar data obtained relative to the NIH as a whole.

Results

For the six most recent years where data were complete, there was a total of 6407 applications submitted. As shown in Figure 1, 44% of the applications were submitted from departments of medicine, 17% from departments of radiology, 16% from departments of surgery, 4% from departments of obstetrics and gynecology, and 6% from departments of pediatrics. Thus, there were nearly three times as many grants submitted from departments of medicine as from departments of surgery. In Figure 2 the overall success rate by department is presented. The success of applications submitted from departments of medicine, pediatrics, and radiology had comparable award rates varying from 34–36%. However, grants submitted from departments of surgery and obstetrics and gynecology were less successful by approximately 10 percentage points. Thus, comparing surgery and medicine, there are not only many more applications being submitted from departments of medicine, their success rate is substantially and significantly higher ($p < 0.001$, chi square test).

In order to determine if trends could be identified, the data were analyzed by individual year. Figure 3 depicts numbers of grants submitted by department from the year 1980 and the year 1985. The only departments with fewer submissions in 1985 than in 1980 were surgery and OB/GYN. The number of grants submitted from departments of medicine increased by 55% (363 to 566) while grants submitted from departments of surgery declined by 17% (203 to 168). Figure 4 depicts the success rate by department for 1980 and 1985. The success rate for all departments decreased to a variable extent. The proportional decreases in success rates were more extreme for departments of surgery and OB/GYN than for departments of medicine. To demonstrate that the 1985 data are truly reflective of at least a short-term trend, data are displayed year-by-year during this interval in Figures 5 and 6. In Figure 5 we show data on submissions as a percentage of the number of applications sub-

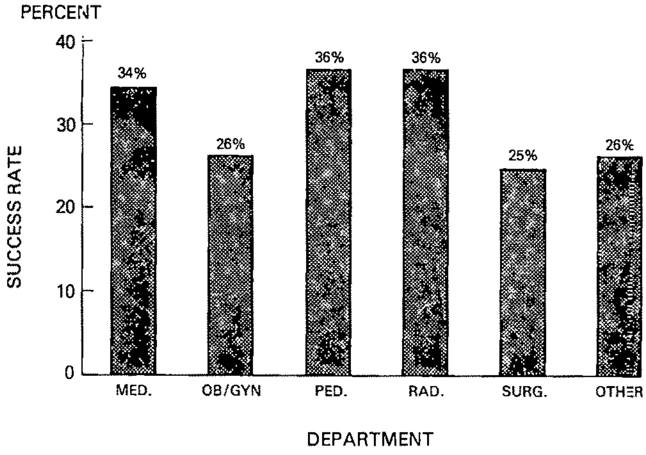

FIG. 2. Success rate (awarded/submitted) of clinical applications by department: 1980–1985 (National Cancer Institute).

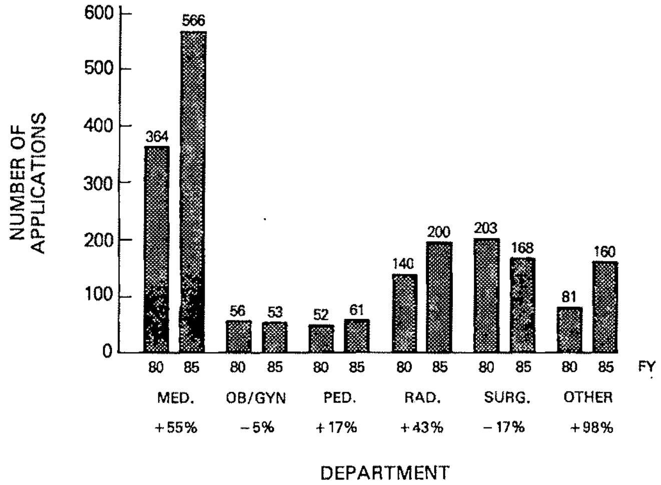

FIG. 3. Number of clinical applications submitted by department: 1980 and 1985 (National Cancer Institute).

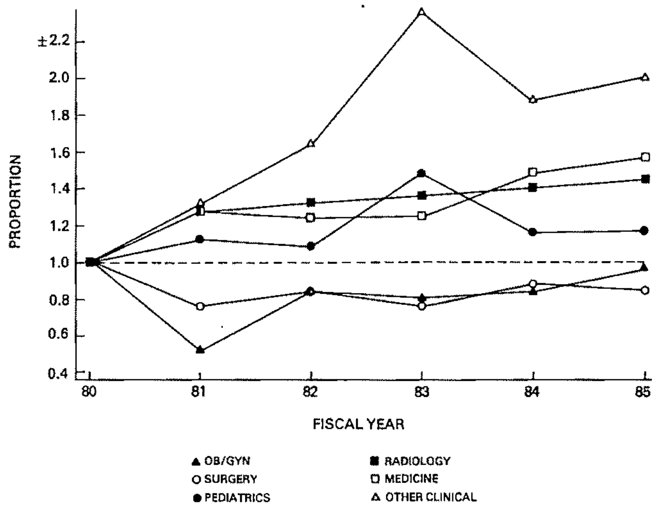

FIG. 5. Trends in number of applications, by department and fiscal year: 1980–1985 (National Cancer Institute).

mitted in 1980, the *baseline* year for this report. The dotted line represents the level of submissions in 1980. As shown, surgery and OB/GYN demonstrated a downward trend (consistently fewer submissions than in 1980) while all other departments have increased their number of applications. Figure 6 shows the year-by-year success rates for the same time interval. While the general pattern is similar for all departments, the success rates for applications from departments of surgery and OB/GYN remain fairly consistently at or near the bottom.

In order to place the data from the NCI into a broader perspective, the data were analyzed relative to the NIH overall trends. Between the years 1980 and 1985, a total of 32,045 applications were submitted by clinical departments. Forty-three per cent of the grants were submitted from departments of medicine, 11% were submitted from departments of pediatrics, 13% from departments of surgery, 6% from departments of radiology, and 5% from departments of OB/GYN (Fig. 7). For departments of surgery and medicine, the patterns within the NCI and the NIH are remarkably similar. Figure 8 displays the success rate by department for the years 1980 to 1985. Again, there is remarkable similarity of the success rates within the NCI and the NIH.

Discussion

The analyses presented in this paper are limited and should not be overinterpreted. The data base is restricted only to university medical schools and does not take into consideration many other institutions supported in part by the NCI. Also, it is not possible to describe specific surgery subspecialties; thus some sub-

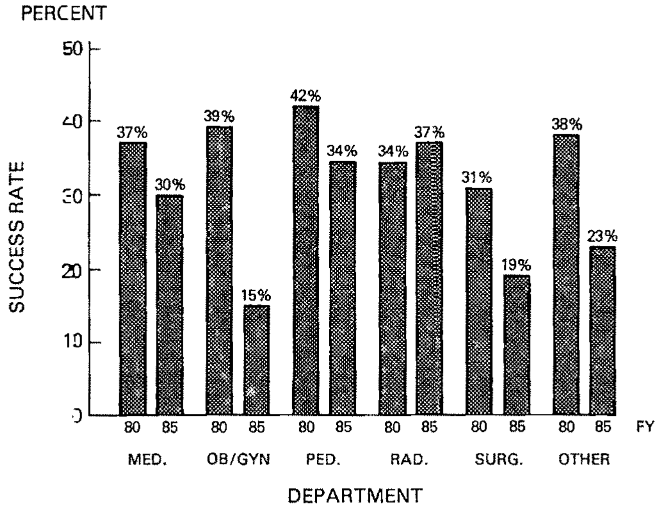

FIG. 4. Success rate (awarded/submitted) of clinical applications by department: 1980 and 1985 (National Cancer Institute).

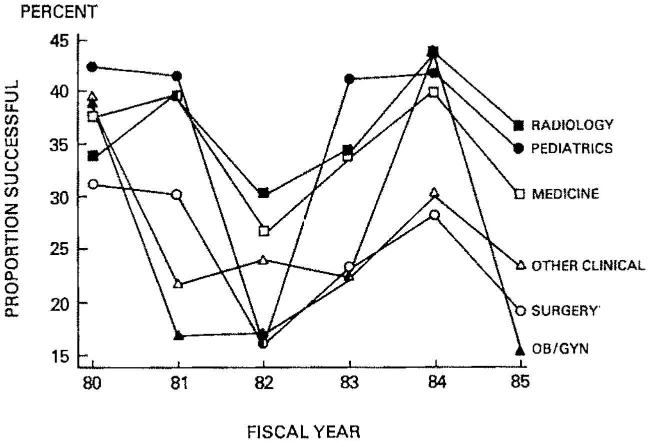

FIG. 6. Proportion of successful applications, by department and fiscal year: 1980–1985 (National Cancer Institute).

specialties may be faring significantly better than others. Additionally, not all cancer-related applications are submitted to the NCI, although the majority are.

The data trends for surgical oncology are disappointing. Departments of surgery have submitted and have been awarded substantially fewer grants over the last 6 years than departments of medicine. In addition, the number of applications submitted from departments of medicine has increased while departments of surgery have submitted fewer grants over the past 6 years. This overall lack of expansion is worrisome because it has taken place in the face of unprecedented scientific and educational opportunities and support mechanisms provided by the Division of Cancer Treatment (DCT) and the Division of Cancer Prevention and Control (DCPC) of the NCI. These NCI initiatives have included the acceptance by DCT of the responsibility for surgical oncology extramural activities as well as the creation of a surgery section in the Clinical Investigations Branch of the Cancer Therapy Evaluation Program. The Surgical Oncology Research Development Subcommittee of the DCT Board of Scientific Counselors has been established, and there have been a number of scientific workshops held. Two major training programs have been instituted by DCPC in conjunction with DCT, the Surgical Oncology Training Grant (T-32), and the Clinical Investigator Award (K-08). The latter was not developed solely for surgeons, but the surgical community was a primary target of interest. Also, there have been several program announcements and requests for applications for planning of surgical oncology programs and for basic research activities.

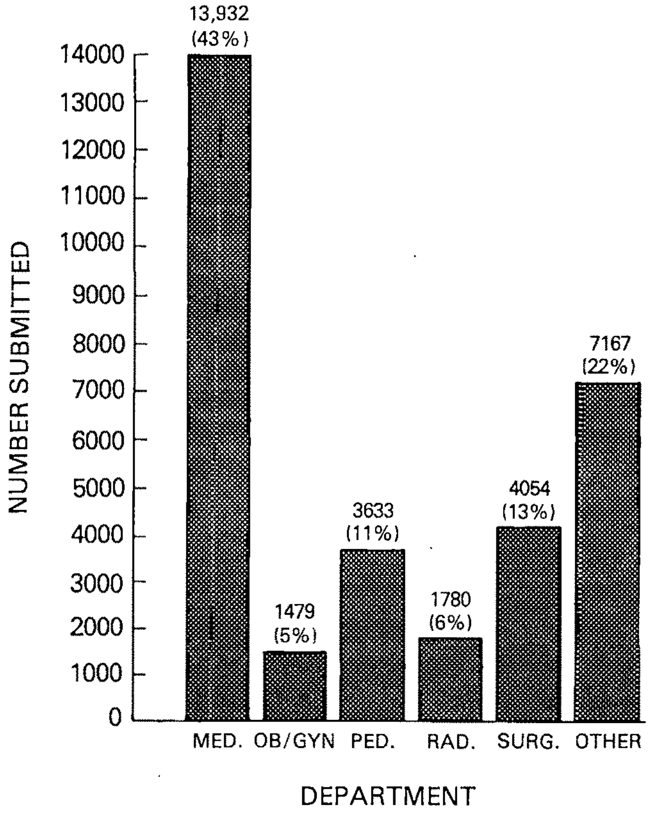

FIG. 7. Number of clinical applications submitted by department: 1980–1985 (National Institute of Health).

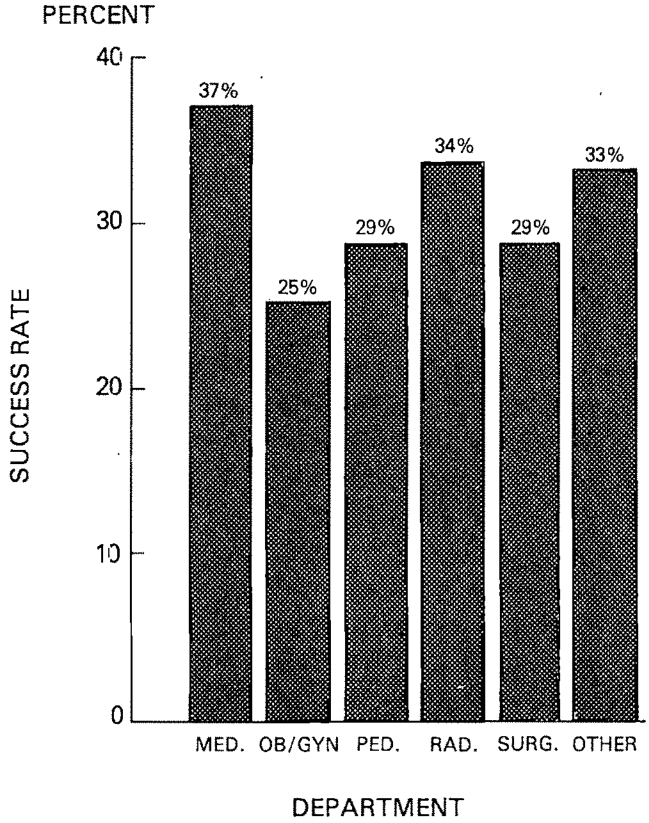

FIG. 8. Success rate (awarded/submitted) of clinical applications by department: 1980–1985 (National Institutes of Health).

A recent publication produced by the Conjoint Council on Surgical Research of the American College of Surgeons is particularly timely and is pertinent to this present analysis.[1] This document consists of reports from six separate committees of special interest including one focusing on cancer. Each committee report includes general observations, opportunities, recommendations, and a summary statement. In addition, appended to this report are two surveys: one conducted by the Society for Academic Surgery and the other by the Society of University Surgeons. Taking this report and the two appended surveys in sum, it would appear that there are some common concerns for the academic surgical community. These include an insufficient number of educational and training opportunities for aspiring academic surgeons; a need to have more protected time allotted for investigators to perform their research; a need for funding sources in addition to those that can be provided by the NIH; an apparent lack of peer recognition of the importance of research and the individual investigator at academic centers; and a perceived need for special study sections to review NIH grant applications.

The solutions to the concerns as outlined both in the Conjoint Council on Surgery Research report, the two appended surveys, and the present study seem fairly obvious. However, the implementation of the solutions may be much more difficult. The NCI has already addressed in part the problem of insufficient education and training opportunities for aspiring academic surgical oncologists. As mentioned earlier, the Surgical Oncology Research Training Grant (SORTG) and the Clinical Investigator Award (CIA) have been created. It is of interest that approximately 13 SORTG applications have been submitted and three have been funded. For a first year effort this is promising. Three CIAs have been awarded. However, in order to award these three grants to surgeons, they were funded out of order according to the payline and as special exceptions.

The need for special study sections constituted to review surgical grant applications has not been well documented but could be investigated further. However, there are two significant problems. Constituting study sections that can adequately review surgical grant applications would be difficult because of the broad research interests of the surgical community. Additionally, as we have shown, there are so few grants submitted, making special review financially unfeasible and the constitution of the study sections difficult. Nevertheless, the NCI is sensitive to this concern and has constituted a special study section to review SORTG proposals on a yearly basis.

The lack of emphasis on surgically sponsored research in academic centers will have to be addressed by the national surgical community. Surgeons committed to research must be provided with both professional and economic rewards by their institutions. Funds and other space manpower resources must be made available to surgeons to permit them to carry out their research activities. In addition, sufficient time for research must be allotted and protected. This obviously has significant financial implications to the department of surgery, medical school, and hospital because of the surgeon's crucial role as an important generator of revenue. It is clear that the decision to implement these policies with a commitment to their success must be made at the highest levels of leadership within departments of surgery and academic institutions.

There is an obvious need for funding to supplement that which may be provided by the NIH. The American Cancer Society, the National Science Foundation, and other organizations have been very helpful in supporting research in the past. Their programs should be carefully scrutinized for opportunities. In addition to these other sources of funding, it is not unreasonable that departments of surgery retain a greater proportion of their clinical earnings for education, training, and research development.

Our data suggest that insufficient numbers of surgical proposals of high merit are being submitted to the NCI and the NIH. This is probably reflective of an insufficient number of academic surgical oncologists with appropriate training and commitment. The academic surgical oncologists who aspire to have research programs need active support from the leadership in their departments of surgery and medical schools, and their time should be guarded to permit them to perform their research duties, the success of which needs appropriate recognition.

Although currently the overall conditions of surgical oncology research and surgical research in general leaves much to be desired, it is very important to recognize that there are areas of success. Several individual surgical oncologists have taken major leadership roles in basic and clinical investigations, developing integrated research programs, and training some fine academic surgeons. These individuals and institutions deserve considerable credit. Nevertheless, there remains much to be done. The NCI, recognizing the primary role played by surgeons in the treatment of cancer patients, remains committed to fostering the research interests of academic surgical oncologists and supporting appropriate research efforts of the surgical oncology community within the bounds of its capabilities.

Acknowledgments

We would like to acknowledge the assistance of Mr. Robert Moore in extracting the relevant data from the information stored by the Division of Research Grants; and Mr. Meyer Gordon of the Office of Associate Director of CTEP in preparation of computer graphics.

Effects of Age and Nutritional Status on Surgical Outcomes in Head and Neck Cancer

BERNARD S. LINN, M.D.,* DAVID S. ROBINSON, M.D.,† and NANCY G. KLIMAS, M.D.‡

From the Veterans Administration Medical Center and the University of Miami School of Medicine, Miami, Florida

Older and younger malnourished and well-nourished head and neck cancer patients scheduled for surgery were studied. More of the young (75%) compared with the old (58%) underwent curative surgery, and only the old with lower clinical stages of cancer were selected. When data on those undergoing surgery were analyzed in regard to older and younger malnourished and well-nourished men, the malnourished old had the poorest surgical outcomes of any group, with significantly more complications and morbidity rates. The well-nourished old had outcomes that did not differ from younger patients. On further examination, 60% of the young malnourished and only 20% of the old malnourished received preoperative enteral or parenteral nutritional support. Findings suggest that more attention to the needs of the older malnourished patients could improve surgical outcomes.

FIFTY YEARS AGO, most surgeons were cautious about operating on elderly patients in the belief that older age was a surgical risk. There is little doubt that age is still a factor in decisions about surgery and that evaluating operative risk is complex. Although morbidity and mortality rates are often similar in old and young after elective surgery, the risk in emergency surgery is much greater in the elderly than in younger patients.[1,2] Furthermore, coexisting morbidity increases with age. Thus, increased surgical risk with age can be attributed in part to multiple pathology, more advanced disease, and more frequent emergency surgery. At the same time, biologic variability increases with age. Although some elderly are frail, most are not. A positive factor for surgery in older patients is often their age, in that they are survivors who have outlived many of their birth cohorts. Numerous studies have shown that good results can be obtained in operating on the elderly when they are properly managed.

Nutritional and immune status are two interrelated factors known to influence surgical outcomes[3,4]; both of these are related to aging. The elderly are more susceptible than younger individuals to nutritional deficiencies because of age-related physiologic changes as well as psychosocial factors.[5] Furthermore, immune function is thought to decline with age.[6] There is increased frequency of cancer with aging, and nutrition and immunocompetence are also associated with cancer.[7]

Malnutrition is known to be high in head and neck cancer. The present study was undertaken to determine whether surgical outcomes differed by older and younger malnourished and well-nourished patients with head and neck cancer.

Methods

Data are taken from a larger 4-year ongoing study of the relationship of nutritional status to surgical outcomes in head and neck cancer patients. The study was initiated in 1984 in Miami at the VA Medical Center. Men admitted for treatment for squamous cell head and neck cancer to surgical wards were selected for study. A total of 120 men (94%) agreed to participate in the study by signing informed consent.

A research nurse collected information describing age, ethnicity, social class, education, marital status, pack/yr of cigarette smoking, diagnosis of alcoholism in the medical record, symptoms, months since onset of symptoms, type and stage of cancer, prior treatments for cancer, and number of days from admission to surgery. In addition, number of current diagnoses and a measure

of severity of illness were obtained using the Cumulative Illness Rating Scale.[8]

Nutritional status was measured 2 days before surgery with a 23-item Protein Energy Malnutrition Scale (PEMS).[9] The scale provides four subscores as well as an overall score for degree of malnutrition. The research nurse obtained anthropometric data and provided ratings for the history and physical subscores on the PEMS. The anthropometric score is derived from per cent ideal body weight, per cent weight loss, triceps skinfold measurement, and midarm muscle circumference. The clinical history score is based on four-point ratings for degree of adequate nutritional intake, excessive nutrient losses, increased metabolic needs, and catabolic medications. The physical examination score is based on four-point ratings for degree of cachexia, hepatomegaly/ascites, muscle atrophy, edema, change in hair/nails, and changes in condition of the skin. A 24-hour dietary intake was recorded for calculation of caloric intake, and a 24-hour urine sample, covering the same time, was ordered for analysis so that creatinine height index and nitrogen balance could be computed. The Multitest CMI (Merieux Institute), consisting of seven delayed hypersensitivity skin tests, was given and read 48 hours later. Blood samples were drawn for laboratory tests. The laboratory score on the PEMS is derived from values for serum albumin, hemoglobin, lymphocyte counts, transferrin, retinol-binding proteins, creatinine height index, nitrogen balance, and skin tests. Higher scores indicate more malnutrition.

The day before surgery, between 8:00 and 10:00 A.M. blood samples were drawn in a heparinized syringe from the patients and their matched controls. The immune tests were done by laboratory personnel blind to patient or control status and to rating time. Blood samples were drawn again 3 and 30 days after surgery and the same immune tests repeated. Lymphocyte response in culture to phytohemagglutinin (PHA), concanavalin A (con A), and pokeweed mitogen (PWM) were studied using a fixed number of purified lymphocytes as previously described.[10] All cultures were done in triplicate, with the means calculated and responses expressed as counts per minute (cpm) in the stimulated minus unstimulated cultures, with log transformation of the cpm for statistical analyses. Neutrophil chemotaxis was used to assess migration of PMN cell according to methods described by Maderazo,[11] using a Boyden chamber and filters 13 mm in diameter with 5-μm pores with and without zymosan-activated guinea pig serum. Means of triplicate counts of stimulated minus unstimulated cultures were used as the neutrophil response to chemotaxis.

Data were also collected describing the operative procedure and outcome of surgery. Operative data included type of operation, times for anesthesia and surgery, blood loss, whether surgery was performed by ENT or general services, level of operating surgeon, and type of anesthesia.

After surgery, patients were monitored daily for 30 days or until discharge or death to determine signs of complications. Severity of each complication was rated by a surgeon who reviewed the daily records of the research nurse at the end of 30 days. A list of possible complications was scored for degree of severity on a 0 (none) to 4 (extremely severe) scale. Other outcome data included number of days from surgery to discharge, whether the patients were readmitted within 90 days after surgery, and number of days from discharge to readmission for those readmitted.

Data were analyzed in a 2 × 2 factorial design for ANOVA, in which one factor was age (older × younger) and the other factor was nutritional status (well-nourished × malnourished). Age was stratified by 60 or over (older) and under 60 (younger). The PEMS score was used to define nutritional status with a score of 8 and over meaning malnourished and a score under 8 meaning well-nourished.

Results

Of the 120 men admitted to be evaluated for possible surgery, 65 were in the older age group (mean age: 64; SD, 5) and 55 were in the younger age group (mean age: 44; SD, 6). Only 72 actually underwent curative surgery with more of the younger (75%) than the older (58%) men being operated upon.

Operated Versus Nonoperated

A higher average clinical stage of cancer (3.3) was associated with operating upon the young and with not operating upon the old (interaction effect of age with surgery was $F = 6.8$, $p < 0.01$). Thus, older patients with a higher clinical stage of cancer were not selected for surgery even though their average stage was identical to that of the younger patients undergoing surgery. The exclusion of higher stage cancers in older patients accounts for the fact that clinical stage differed significantly by age ($F = 5.4$, $p < 0.01$), with the old being 2.7 and the young 3.3. Although the older group had a greater number of diagnoses than the younger group (4.9 *vs.* 2.6; $F = 7.8$, $p < 0.01$), number of diagnoses did not discriminate significantly between those who were and were not operated upon (3.3 *vs.* 4.2, with those having surgery having more diagnoses). Severity of illness scores did not differ either by age or having surgery. Degree of malnutrition did not differ by age groups; however, there was a trend toward those who were less well-nourished being excluded from surgery, particularly in the older group, but this was not statistically significant. Prior treatment with radiation did not differ

significantly, with about one fourth of all groups operated or not having received radiation. However, none of the older, as compared with 17% of the younger patients, had received prior chemotherapy ($F = 7.2$, $p < 0.01$). Records of each of the patients excluded from surgery were reviewed. In the groups, 22% of the old and 33% of the young were not operated upon because their biopsies indicated unresectable tumors. Also, one patient in each group expired before surgery. The remaining patients were referred for either radiation or chemotherapy as the treatment of choice, except for one patient in each group who selected one of these treatments rather than undergoing extensive surgery. In summary, there were no clear indications as to why fewer of the old than the young were selected for surgery. The remaining results focus upon those patients who had surgery.

Background Characteristics

Table 1 shows characteristics of the sample by age and nutritional status. It can be seen that none of the variables differed significantly at a statistical level by older and younger age of the patients. Pack/years of smoking was significantly higher among the well-nourished compared with the malnourished patients ($p < 0.01$). In addition, less of the malnourished young but more of the malnourished old were currently married ($p < 0.05$).

Symptoms and Types of Cancer

Table 2 shows months from onset of symptoms to diagnosis of cancer, types of symptoms, and types of cancer for the four groups. Older men came in sooner than younger men after onset of symptoms, with an average of about 2.9 months in the old as compared with about 5 months in the young ($p < 0.05$). This, however, may also reflect the lower clinical stage of cancer in the old than in the young who received surgery. More of the young than old had symptoms of trouble swallowing ($p < 0.05$) and weight loss ($p < 0.001$). A number of symptoms differed in malnourished *versus* well-nourished groups: nausea ($p < 0.05$), hoarseness ($p < 0.01$), trouble swallowing ($p < 0.01$), and weight loss ($p < 0.001$). There were no statistically significant interaction effects of age with malnutrition, indicating that older and younger malnourished differed from well-nourished in a similar manner.

In regard to types of head and neck cancer, some of the younger but none of the older patients had tonsillar carcinoma ($p < 0.05$). Likewise, there were more cancers of the hypopharynx in malnourished than well-nourished patients ($p < 0.05$). Again, no interaction effects of age and nutritional status were found.

Nutritional Status

Table 3 shows the total PEMS scores for old and young malnourished and well-nourished patients. Although the proportion of patients who were malnourished did not differ by age (58% of old and 55% of young were malnourished), there was a significant interaction effect of age with nutritional status, in that the malnourished old had higher scores than any other group ($p < 0.05$). It can be seen that the old malnourished became more malnourished (about the same degree more as well-nourished patients) after surgery; however, the malnourished younger patients remained essentially at the same level of malnutrition.

Immune Status

Table 4 shows that lymphocyte responses to con A were lower in the old malnourished patients than in any other group after surgery. As expected, malnourished

and well-nourished patients differed significantly, with malnourished having lower immune function as reflected by lymphocyte responses to con A and by anergy. Doses yielding maximal responses were selected for analysis of lymphocyte function. Although response to delayed hypersensitivity skin testing was considered part of nutritional status measurement, it is shown here since it demonstrated the same *in vivo* cellular immune function pattern as that found for the *in vitro* lymphocyte response, with 60% of the old malnourished and 20% of the young malnourished being anergic (no response to all seven antigens).

Surgical Outcomes

Table 5 shows how the groups compared in regard to surgical outcomes. Days after surgery in the hospital were significantly more for malnourished than well-nourished patients ($p < 0.05$). Furthermore, more malnourished than well-nourished had greater degrees of postoperative complications ($p < 0.05$). However, significantly more of the old malnourished had more complications and significantly more of the old malnourished died within 1 year after surgery than any other group (both significant at the 0.05 levels). The relationship between nutritional status before surgery and surgical outcomes were examined. Greater degree of malnutrition, as reflected by the PEMS score, was correlated significantly with postoperative complications ($r = .42$, $p < 0.01$) and death within the year ($r = .59$, $p < 0.01$).

Preoperative Nutritional Support

In trying to account for the fact that the old malnourished became more malnourished after surgery while the younger malnourished did not, as well as for why the old

malnourished had the poorest outcomes of any group, the question of nutritional intervention before surgery was examined. None of the well-nourished in either age group received any type of nutritional support. Sixty per cent of the younger malnourished patients received either enteral or parenteral nutritional support before surgery. On the other hand, only 20% of the older malnourished patients received nutritional intervention before surgery.

Discussion

The major finding was that malnourished older patients had poorer surgical outcomes than any other group. The well-nourished elderly were similar in postoperative morbidity rates to younger patients. Since preoperative level of malnutrition was associated significantly with postoperative complications and death within 1 year, it seems likely that improving nutritional status before surgery, particularly in the elderly, might lead to decreased postoperative morbidity rates. This presents a dilemma for two reasons. One is that there is some suggestion here that the attitudes of staff about operating on the elderly and offering nutritional intervention may have played a role in their poorer surgical outcomes. If only older patients with lower clinical stages of cancer were selected for surgery then there is some systematic age bias in selection of patients. Further, if almost none of the malnourished old, but a sizeable proportion of the malnourished young, received nutritional intervention, and taking into account that the malnourished old were more malnourished than the malnourished young, then again there appears to be some age bias in the selection, unfortunately (in this case) for a clinical problem (malnutrition) that is remediable. What this suggests is that attitudes of the staff about treating the elderly may need to be explored further.

If chronologic age, rather than physiologic age, is the determinant of medical care, then the elderly may be given care that can result in premature morbidity and mortality rates.[12] There are additional suggestions of this

from other studies. One study[13] found that elderly patients with cancer received less curative treatments than younger patients with cancer even after taking stage of the disease into account. Likewise, a study[14] of 1680 women with breast cancer treated in 17 hospitals showed a linear trend for older patients to receive fewer services such as biopsies, number of lymph nodes examined, chemotherapy, and radiation therapy, even though stage of cancer and estrogen receptor status were not associated with age. Another recent study[15] controlled for comorbidity, functional status, and tumor stage, as well as for type and size of seven hospitals from which 374 cancer patients were selected. They found that even after controlling for all of these factors, age itself affected medical care in that physicians provided less than optimal care for older patients even with mild or no comorbid disease. Wetle[16] concluded that lack of data about treatment effectiveness and side effects for older patients made clinicians reluctant to use new treatments with the elderly or overly cautious by using less than optimal dosages. In turn, this leads to a self-fulfilling prophecy in which older patients treated for cancer *do not do well* because appropriate treatment was not provided. We have recently reported[17] that medical student attitudes about surgery in the elderly could be changed positively by a better understanding of the normal aging process and the need to evaluate each older person individually in regard to surgical risk based on his or her biologic and not chronologic age. Whether some emphasis in continuing medical education for staff or in the quality assurance review and feedback to staff would change attitudes about treating the elderly could be tested.

There is, however, another complicating factor that needs to be considered. Even if attitudes about operating on the elderly were improved and staff were motivated to offer nutritional intervention, the latter may be difficult to accomplish. Cost containment goals and diagnostic related groups (DRGs) have led to patients coming in only a day or two before elective surgery. We have found[18] that head and neck cancer patients admitted since institution of DRGs had significantly more malnutrition at the time of surgery and more postoperative complications than patients admitted before institution of DRGs. There is currently no system for reimbursement under DRGs for treating malnutrition. Thus, if preoperative nutritional support is needed, it may have to be offered in the home before hospital admission. The lack of time for intervention in the hospital applies equally to the young and old. However, there have been questions raised[19] about operations for the elderly and their necessity, with suggestions made that a third of the procedures may be unnecessary and that second opinions should be required for operations in the elderly. If such attitudes center only around the old, this can lead in a dangerous direction as a means of cost containment, because death, of course, can become the ultimate economy. The longer the elderly survive, the more costly their care.

At the same time that one might argue for equal treatment for all regardless of age, there are questions about the value of nutritional intervention in cancer. The role of cancer cachexia is not fully understood, particularly in how metabolism and immune function may be related. Malnutrition is known to suppress immune function. There is agreement that both malnutrition and immune function before surgery are associated with postoperative complications. However, studies have not clearly demonstrated that nutritional intervention in cancer patients can improve survival. There are questions as to whether total parenteral nutrition or overnutrition may in fact promote tumor growth.[20] The lack of effect of aggressive nutritional therapy on survival, however, should not be used to deny any cancer patient nutritional support during the course of illness. A better understanding, however, is needed about the effects of nutritional intervention, and most would agree that it should be used only for malnourished patients and perhaps then only in amounts adequate to supply needs and not tumor growth.

The comparison of old and young head and neck cancer patients showed several differences that require further study. Older patients seem to seek medical care earlier for symptoms than younger ones. The older patients also had fewer tonsillar cancers, which raises a question of whether this might be associated with the common practice of removing tonsils when the older men were children. Older patients never received preoperative chemotherapy, which also raises the question of possible age bias in clinical management. Why more pack/years of smoking was associated with being well-nourished, instead of being malnourished, cannot be answered, but the magnitude of the difference was 20 pack/years and occurred in both old and young groups between malnourished and well-nourished groups. Overall, there were perhaps more similarities than differences between old and young head and neck cancer patients. Mortality rates were very high in the malnourished old (50%) but lowest of any group in the well-nourished old (11%). In general, the findings suggest that more attention to the needs of the elderly in areas that could improve surgical outcome such as nutritional repletion might prove beneficial.

Metabolic Intervention in Surgical Patients

An Assessment of the Effect of Somatostatin, Ranitidine, Naloxone, Diclophenac, Dipyridamole, or Salbutamol Infusion on Energy and Protein Kinetics in Surgical Patients Using Stable and Radioisotopes

JAMES H. F. SHAW, M.D., F.R.A.C.S.* and ROBERT R. WOLFE, PH.D.†

From the University Department of Surgery, Auckland Hospital, Auckland, New Zealand, and the Metabolic Research Department, University of Texas, Medical Branch, and the Shriners Burn Unit, Galveston, Texas†*

We have assessed the effect of a variety of forms of metabolic intervention on both energy and protein metabolism in 44 severely ill surgical patients. The patients were studied either in the basal state or while receiving total parenteral nutrition (TPN), and the metabolic effects were assessed using the primed-constant infusion of a combination of stable isotopes and radioisotopes. Somatostatin infusion, either in the basal state or in the TPN, did not change glucose kinetics, but there was a significant decrease in the rate of net protein catabolism (NPC). In the basal studies the rate of NPC decreased from 3.4 ± 0.7 g/kg/d to 2.9 ± 0.7 g/kg/d ($p < 0.002$), while in the TPN patients the corresponding values were 1.48 ± 0.61 g/kg/d and 1.10 ± 0.50 g/kg/d, respectively ($p < 0.005$). Histamine type 2 blockade with ranitidine did not significantly alter glucose kinetics, but in both the TPN patients and in the basal state ranitidine was associated with a significant decrease in the rate of NPC. In the basal state rate of NPC was 2.44 ± 0.53 g/kg/d and during ranitidine infusion the value was 2.08 ± 0.42 g/kg/d ($p < 0.04$). Naloxone infusion did not alter glucose kinetics, but there was a significant decrease in the rate of NPC from a basal value of 2.6 ± 0.6 g/kg/d to 2.3 ± 0.5 g/kg/d ($p < 0.04$). The infusion of the prostaglandin antagonists diclofenac or dipyridamole resulted in increases in the plasma insulin level, and as a result glucose turnover decreased in both groups. In the diclofenac group the rate of glucose turnover decreased from 14.4 ± 1.7 μmol/kg/min to 12.6 ± 1.3 μmol/kg/min ($p < 0.02$). Neither prostaglandin antagonist resulted in any significant change in the rate of NPC. Beta-adrenergic stimulation with salbutamol resulted in a significant increase in glucose turnover from 12.1 ± 1.1 μmol/kg/min to 13.4 ± 0.9 μmol/kg/min ($p < 0.02$), and the rates of appearance (Ra) of both alanine and free fatty acids (FFAs) also increased. Alanine Ra increased from 11.7 ± 2.5 μmol/kg/min to 12.8 ± 3.0 μmol/kg/min, and the corresponding values for FFA turnover were 7.6 ± 1.1 μmol/kg/min and 10.3 ± 2.1 μmol/kg/min ($p < 0.03$), respectively. Salbutamol infusion did not result in any significant change in the rate of NPC. We conclude from these studies the following: (1) The infusion of somatostatin, ranitidine, or naloxone results in a significant decrease in the rate of NPC in severely ill surgical patients both in the basal state and during TPN. (2) The aforementioned three agents do not influence glucose kinetics in any major way. (3) The infusion of prostaglandin antagonists does not result in any significant decrease in the rate of NPC, but insulin and cortisol levels change and glucose production decreases. (4) The infusion of the beta-agonist salbutamol results in the mobilization of both glucose and FFA, but there is no associated conservation of protein.

TOTAL PARENTERAL NUTRITION (TPN) has been widely used for a variety of reasons since its introduction approximately 25 years ago.[1] In a general sense TPN is a useful supportive modality especially in severely ill surgical patients who have a gut that is either blocked, inflamed, or patients who simply cannot cope.[2] Unfortunately, it has recently become apparent that although the use of TPN results in a decrease in the protein loss that accompanies critical surgical illness, only a minority of patients are rendered anabolic.[3–6] Patients with pure uncomplicated starvation are generally able to gain whole body protein with the use of TPN,[6,7] and upper gastrointestinal cancer patients can advance to a nutritional endpoint where they do not lose any more protein (the rate of whole body protein synthesis [WBPS] approximately equals the rate of whole body protein catabolism [WBPC]).[4,8] However, in severely stressed patients suffering from either trauma[9] or sepsis,[3,6] although the use of TPN results in a marked increase in WBPS, and as a result a major decrease in the rate of net protein loss, these patients remain in a state where net protein loss continues albeit at a slower rate than in the absence of TPN. vivo neutron activation techniques have estimated that critically ill septic and/or trauma patients experience a loss of approximately 10% of their total body protein over a 2-week period despite the use of apparently state-of-the-art TPN.

The regulation of energy and protein metabolism in severely ill surgical patients has not been widely studied. Insulin is thought to have an anabolic role similar to the situation in normal humans, but there is a substantial body of data showing that in severely ill surgical patients insulin is less effective metabolically than in normal humans.[3,11,12] Glucagon cortisol and the catecholamines are known to be general promoters of the catabolic response to sepsis and/or trauma.[13,14] In particular both cortisol and glucagon are known to be promoters of both protein catabolism and gluconeogenesis from amino acids.[13,14] In addition, the beta-adrenergic nervous system is important in the promotion of fat mobilization,[15,16] while the alpha-adrenergic nervous system acts to inhibit lipolysis and promote proteolysis and glucose turnover.[15-17] The prostaglandin system, the endorphin system, and histamine are also thought to be involved in the regulation of the catabolic response, but the roles played by these agents are less clear.[13,14,18-22] Prostaglandin blockade with nonsteroidal anti-inflammatory agents such as ibuprofen or diclofenac has been shown to minimize the metabolic abnormalities that occur as a consequence of endotoxic shock,[21,22] but little work has been done to assess the effect of these type of agents in severely ill patients. Blocking the release of endorphins from the brain with the use of naloxone has been shown to improve survival in animals suffering from experimental shock[20]; however, few studies have been performed in severely ill patients. In addition, although much is known about the role of histamine as a mediator of the inflammatory response, its role in the mediation of the catabolic response to stress is less clear. Brackett et al.[18] have, however, recently shown that the use of H_1 and H_2 histamine receptor antagonists minimized the hemodynamic and metabolic abnormalities associated with endotoxemia in the conscious rat.

Because most critically ill surgical patients continue to have ongoing high rates of WBPC despite the use of TPN[3-6] and as a result of this an ongoing rate of protein loss, we have performed a series of studies to assess the effect of a variety of forms of metabolic intervention to conserve host tissue in severely ill surgical patients. These studies have been performed both in the basal state and also on patients receiving TPN. In particular, we have assessed the metabolic and hormonal changes associated with the following perturbations: somatostatin infusion to decrease insulin, growth hormone (HGH), and glucagon availability[23]; histamine type 2 (H_2) blockade using the infusion of ranitidine[18,24]; naloxone infusion to decrease endorphin availability[19]; and two forms of prostaglandin blockade using either diclofenac or dipyridamole.[20-22,24,25] In addition, in view of the fact that fat is probably a preferred fuel in severely stressed patients,[25-29] and because fat mobilization is a beta-adrenergic effect,[15,16] we have also assessed the metabolic and hormonal response to beta-adrenergic stimulation by infusing the beta-agonist salbutamol.

Materials and Methods

Studies were performed in 44 severely ill surgical patients. Most of the patients were suffering from either pancreatitis, some form of cancer, sepsis, or trauma, and the clinical details of the group are summarized in Table 1. In all cases the patients were at least 12 hours postabsorptive at the time of study.

The study was approved by the institutional board at Auckland Hospital, and the use of radioisotopes was approved by the National Radiation Laboratory (New Zealand).

Experimental Protocol

All experiments involved the infusion of isotopes and the collection of blood samples.

The experiments each consisted of two periods (periods 1 and 2). At the start of period 1 a primed-constant infusion of isotopes was started and maintained for the duration of the study. Period 1 lasted for 180 minutes and blood samples were taken over the last 60 minutes. During the 120 minutes of period 2, in both the patients and volunteers the isotopic infusion was continued, and the system was perturbated using one of seven types of metabolic intervention. Blood samples were taken again during period 2. In addition, ten infusions were performed where there was no perturbation in period (isotopes alone were infused throughout).

Types of Metabolic Intervention Employed

In period 2 of each study there was either no perturbation (control protocol) or one of seven perturbations was induced. These were: (1) the infusion of somatostatin (0.15 μg/kg/min) in order to decrease glucagon, HGH, and insulin availability; (2) the infusion of somatostatin and insulin in order to selectively reduce the plasma levels of HGH and glucagon while maintaining the plasma insulin level approximately constant. Here the somatostatin infusion rate was as for (1), and, in addition, insulin was infused at approximately 0.05 mIU/kg/min; (3) the infusion of the histamine type 2 blocking agent ranitidine at a rate of 6 μg/kg/min in order to induce a state of partial histamine blockade; (4) the infusion of naloxone at a rate of 0.1 μg/kg/min in order to decrease endorphin availability; (5) the infusion of the beta-adrenergic agonist salbutamol at a rate of

SOM = somatostatin infusion.
SOM-INS = somatostatin-insulin infusion.
RAN = ranitidine infusion.
SAL = salbutamol infusion.
NARC = naloxone infusion.
PERS = dipyridamole infusion.
VOLT = diclofenac infusion.
TPN = patient receiving TPN during study.

0.12 μg/kg/min in order to promote beta-adrenergic activity; (6) the infusion of either diclofenac (0.01 mg/kg/min) or dipyridamole (1.2 μg/kg/min) in order to inhibit prostaglandin synthesis.

The aforementioned types of metabolic intervention were performed in patients in the basal state (at least 12 hours postabsorbtive). Furthermore, the effect of either somatostatin infusion or ranitidine infusion was assessed in patients established on TPN. The patients were studied when they had been on TPN on average for 1 week, protein was provided at 2 g/kg/d, and calories were provided at a rate of 40 kcal/kg/d with 50% of calories being provided as fat and 50% as glucose. The details of the various perturbations performed in each patient are shown in Table 1.

Isotopic Infusions and Calculations

A combination of stable and radioisotopes were used. Glucose kinetics were determined using the primed-constant infusion of 6-^{3}H glucose as we have described before,[30] and urea kinetics were determined using the primed-constant infusion of ^{14}C urea as we have described previously.[30,31] Alanine rate of appearance was determined using the primed-constant infusion of 3-^{13}C alanine as described elsewhere,[32] and FFA kinetics were quantitated using 1-^{13}C-palmitic acid as described elsewhere.[33]

The primed-constant infusion of either 15N lysine or 1-^{13}C leucine was used to determine amino acid turnover,[34] and from these data rates of WBPS and WBPC

were determined as described previously.[35] Rates of NPC were calculated from the urea rate of appearance data as described previously.[30,32]

Rate of appearance calculations were performed using the Steele equation[36] in the case of radioisotopes, and for 15N and ^{13}C labeled tracers the Steele equation was modified appropriately.[30,31,33,34]

Statistical Analyses

Because there were no significant changes in either kinetic or hormonal levels between period 1 and 2 in the control studies, the data obtained in period 2 of each study were compared with the corresponding period 1 data using a paired t-test. In addition, the data obtained in the various groups were compared using ANOVA.

Analysis of Samples

Blood samples were immediately chilled and later centrifuged to separate the plasma.

Plasma glucose specific activity and urea specific activity were determined as described elsewhere.[30] We have previously described the methods by which plasma 15N lysine and ^{13}C leucine enrichment were determined,[3,4,34] as well as the method by which the enrichment of ^{13}C palmitate was determined.[33]

Serum levels of insulin, growth hormone, and cortisol were determined by radioimmunoassay.[37-39]

Results

Hormones

Somatastatin infusion resulted in a significant decrease in the plasma levels of insulin, glucagon, and HGH. The plasma level of cortisol did not change in any of the protocols in which somatostatin was infused (Table 2).

Ranitidine infusion did not significantly change the plasma levels of cortisol or insulin in the basal state or during TPN (Table 2).

Neither the infusion of naloxone nor salbutamol resulted in any significant change in the plasma levels of insulin or cortisol. However, the infusion of both diclofenac and dipyridamole resulted in an increase in the plasma insulin level ($p < 0.05$ for diclofenac, and $p < 0.08$ for dipyridamole). In addition, dipyridamole infusion resulted in a significant decrease in the plasma cortisol level ($p < 0.03$) (Table 2).

Somatostatin Infusion

When somatostatin alone was infused there was no significant change in either the plasma glucose concentration or in the rate of glucose turnover. As a consequence, the rate of glucose clearance also did not change. The basal rate of glucose turnover in these studies was 19.0 ± 3.6 µmol/kg/min, and during somatostatin infusion the value was 20.1 ± 3.2 µmol/kg/min. When somatostatin was infused in the TPN patients the effect was similar; there was no significant change in the plasma glucose level or in the rate of glucose turnover or glucose clearance (Fig. 1).

When both somatostatin and insulin were infused there was a selective reduction in the plasma levels of glucagon and HGH while the plasma insulin level did not change significantly. In this setting the plasma glucose level decreased from 6.9 ± 0.7 µmol/mL to 4.8 µmol/mL ($p < 0.05$), and the rate of glucose turnover decreased from 17.6 + 2.2 µmol/kg/min to 11.1 ± 2.5 µmol/kg/min ($p < 0.01$). The rate of glucose clearance also decreased from 2.7 ± 0.3 mL/kg/min to 2.3 ± 0.3 mL/kg/min ($p < 0.04$) (Fig. 1).

Somatostatin infusion resulted in a decrease in urea turnover in each of the three protocols. When somatostatin was infused alone, the rate of urea turnover decreased from 13.4 ± 2.9 µmol/kg/min to 11.8 ± 2.0 µmol/kg/min ($p < 0.002$). The infusion of somatostatin and insulin resulted in a similar magnitude of change ($p < 0.007$); the basal value was 11.3 ± 2.5 µmol/kg/min

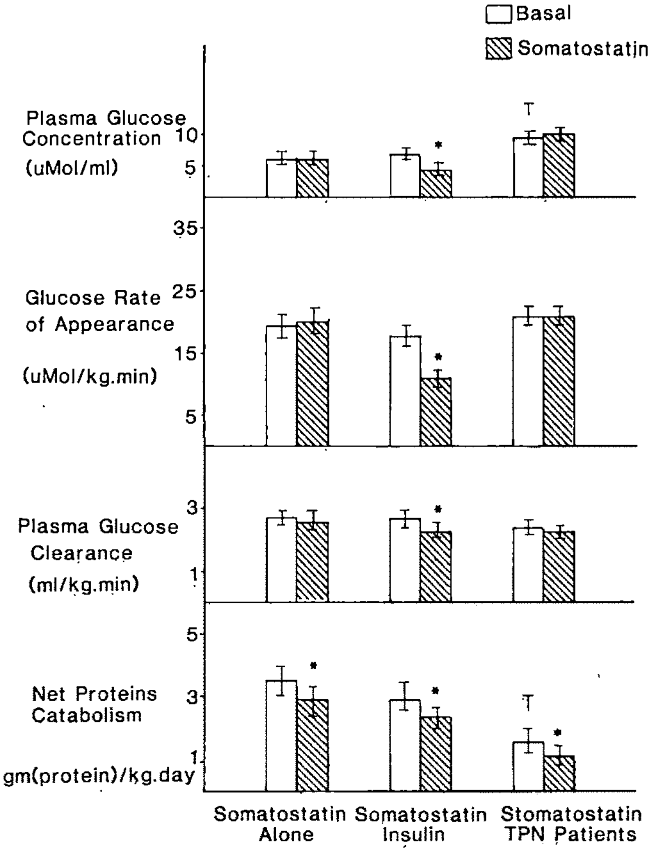

FIG. 1. Glucose kinetics and NPC in patients and the effect of somatostatin infusion. * Significantly different from preceding value ($p < 0.05$ or better). T, significantly different from corresponding basal value ($p < 0.05$ or better).

and the period 2 value was 9.5 ± 2.1 μmol/kg/min. In the TPN patients the basal rate of urea turnover was 14.0 ± 2.8 μmol/kg/min and during somatostatin infusion this decreased to 12.5 ± 2.5 μmol/kg/min ($p < 0.005$).

The period 1 and period 2 values for NPC calculated from the urea kinetic data were as follows: somatostatin infusion alone, 3.4 ± 0.7 and 2.9 ± 0.7 g/kg/d ($p < 0.002$); somatostatin/insulin infusion, 2.8 ± 0.7 and 2.4 ± 0.5 g/kg/d ($p < 0.007$); somatostatin/TPN, 1.47 ± 0.61 and 1.10 ± 0.50 g/kg/min ($p < 0.05$). The basal value for the rate of NPC in the TPN patients (1.47 ± 0.62 g/kg/day) was significantly lower ($p < 0.01$) than the overall value for NPC in the basal state (3.1 ± 0.8 g/kg/d).

The basal rate of WBPC in the TPN patients overall was 7.3 ± 1.5 g/kg/d (NS, less than the basal value). In the TPN patients in whom the effect of somatostatin infusion was assessed, the basal value for WBPC was 8.2 ± 2.1 g (protein)/kg/d, and during somatostatin infusion this decreased to 6.6 ± 1.6 g/kg/d ($p < 0.03$) (Fig. 2). Somatostatin infusion did not significantly alter the rate of WBPS in the TPN patients.

Ranitidine Infusion

Ranitidine infusion did not alter either the plasma glucose level or the rate of glucose turnover when infused either in the basal state or during TPN. In the basal state the rate of glucose turnover was 17.3 ± 2.8 μmol/kg/min, and during ranitidine infusion the corresponding value was 17.2 ± 3.0 μmol/kg/min. In the TPN patients the basal rate of glucose turnover was 18.6 ± 1.7 μmol/kg/min, and during ranitidine infusion the value was 17.1 ± 1.5 μmol/kg/min (Fig. 1).

Ranitidine infusion resulted in a suppression of the rate of NPC. The basal rate of NPC for the ranitidine group as a whole was 2.44 ± 0.53 g/kg/d, and during ranitidine infusion this decreased to 2.08 + 0.42 g/kg/d ($p < 0.03$).

In the TPN patients ranitidine infusion was associated with a decrease in urea turnover from 11.9 ± 1.6 μmol/kg/min to 10.5 μmol/kg/min. In these patients the glucose infusion rate was 3.3 ± 0.3 mg/kg/min, the lipid infusion rate (20% lipid emulsion) was 0.007 ± 0.0003 mL/kg/min, and the protein infusion rate was 1.9 ± 0.3 g/kg/d. Under these circumstances this decrease in urea turnover represented a significant decrease in the rate of NPC from 1.10 ± 0.33 g/kg/d to 0.88 ± 0.25 g/kg/d ($p < 0.05$) (Fig. 2).

The basal rate of WBPC in the ranitidine infusion group was 3.9 + 0.8 g/kg/d, and during ranitidine infusion this decreased to 3.2 + 0.5 g/kg/d ($p < 0.03$). The basal rate of WBPS calculated from the WBPC and NPC data did not change significantly following ranitidine infusion (Fig. 3).

The rate of WBPC in the TPN patients prior to ranitidine infusion was 6.5 + 1.0 g/kg/d, and during ranitidine infusion the value was 5.5 + 0.8 g/kg/d ($p < 0.02$). The rate of WBPS did not change significantly during ranitidine infusion in the TPN patients (Fig. 3).

Salbutamol Infusion

Salbutamol infusion resulted in a significant increase in both the plasma glucose concentration and in the rate of glucose turnover. The basal value for glucose concentration was 7.2 ± 0.6 μmol/mL, and in period 2 the value was 7.9 + 0.6 μmol/mL. The basal rate of glucose turnover was 12.1 ± 1.1 μmol/kg/min, and during salbutamol infusion this increased to 13.4 ± 0.9 μmol/kg/min ($p < 0.02$). This increase in glucose turnover was associated with an increase in the rate of alanine appearance into the plasma; the basal rate of alanine appearance was 11.7 ± 2.5 μmol/kg/min and during salbutamol infusion this increased to 12.8 ± 3.0 μmol/kg/min. The rate of FFA appearance also increased during salbutamol infusion; the basal value was 7.6 ± 1.1 μmol/kg/min and during salbutamol infusion this increased to 10.3 ± 2.1 μmol/kg/min ($p < 0.04$).

The basal rate of urea turnover in the salbutamol

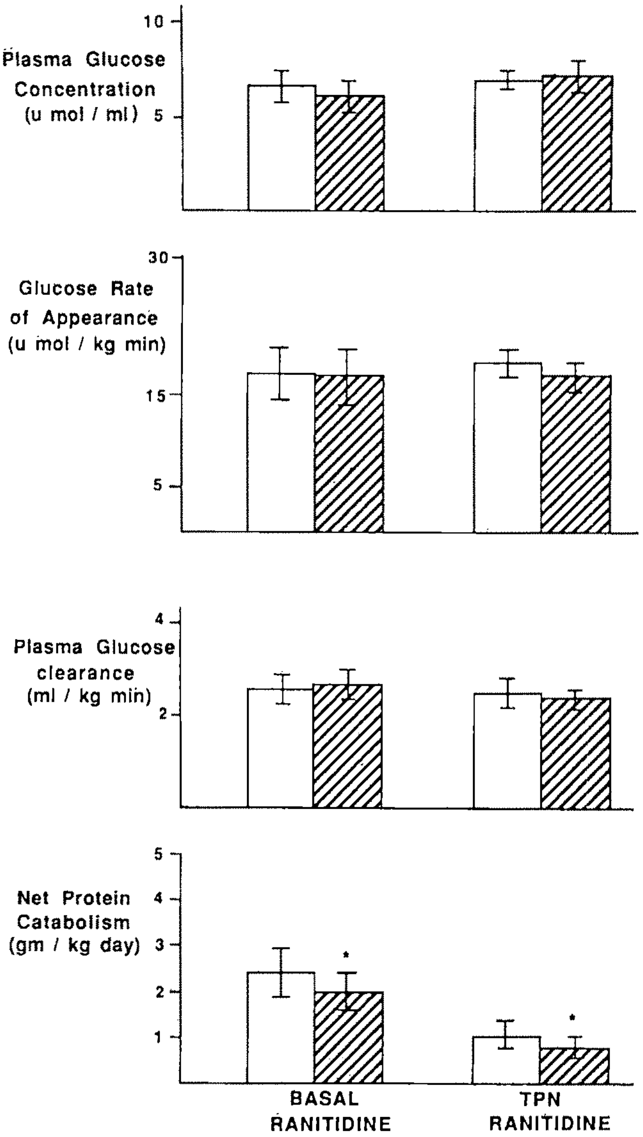

FIG. 2. Glucose kinetics and NPC in patients and the effect of ranitidine infusion. * Significant difference compared with preceding value ($p < 0.05$ or better).

group was 7.7 ± 1.8 μmol/kg/min, and during salbutamol infusion the value was 7.3 ± 1.5 μmol/kg/min (NS) (Fig. 4).

Naloxone Infusion

Naloxone infusion was not associated with any significant change in either the rate of glucose turnover or glucose clearance. The basal rate of glucose turnover was 18.5 ± 2.0 μmol/kg/min and during naloxone infusion the corresponding value was 17.5 ± 3.0 μmol/kg/min. The basal value for plasma glucose concentration was 7.9 ± 0.6 μmol/mL, and in period 2 the value was 7.8 ± 0.4 μmol/mL.

The basal rate of urea turnover was 10.3 ± 2.4 μmol/kg/min, and during naloxone infusion this decreased to 9.3 ± 2.1 μmol/kg/min ($p < 0.04$). From these values

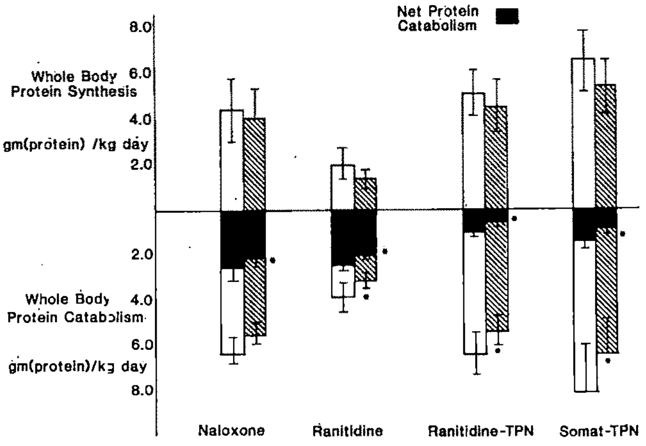

FIG. 3. Whole body protein kinetics in patients and the response following various types of metabolic intervention. Values are given as mean ± SEM. * Significantly different from preceding value ($p < 0.05$).

the basal rate of NPC was 2.60 ± 0.60 g/kg/d, and during naloxone infusion this decreased significantly to 2.34 ± 0.53 g/kg/d ($p < 0.04$). The basal rate of WBPC was 6.3 ± 0.9 g/kg/d, and during naloxone infusion this decreased to 5.7 ± 0.9 g/kg/d (Figs. 3 and 4).

Diclofenac Infusion

The basal rate of glucose turnover in these patients was 14.4 ± 1.7 μmol/kg/min, and during diclofenac

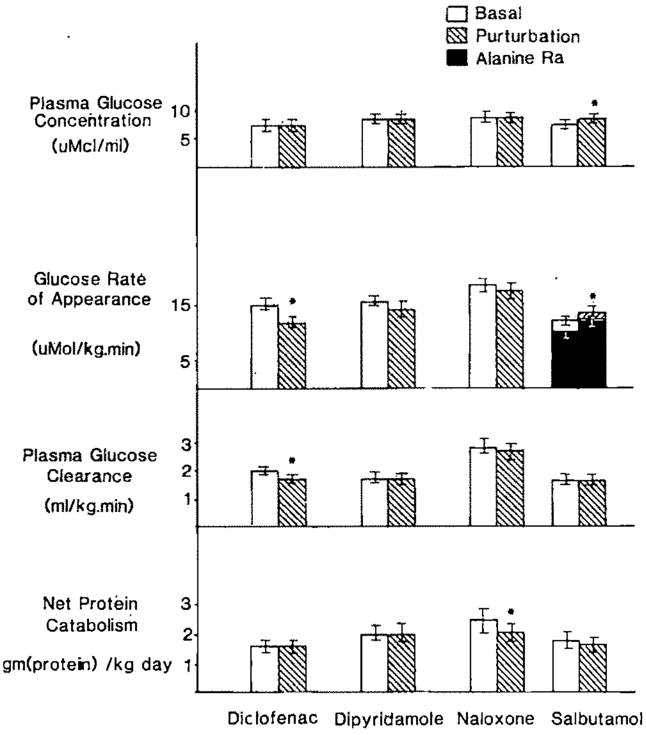

FIG. 4. Glucose kinetics and NPC in surgical patients and the effect of pharmacologic manipulation. * Significantly different from preceding value ($p < 0.05$ or better).

(VOLT) infusion this decreased significantly to 12.6 ± 1.3 μmol/kg/min ($p < 0.02$). The basal rate of plasma glucose clearance was 2.0 ± 0.1 mL/kg/min, and during VOLT infusion this decreased to 1.8 ± 0.1 mL/kg/min ($p < 0.05$). As a result, the plasma glucose concentration did not change significantly. The period 1 and period 2 values were 7.2 ± 0.8 μmol/mL and 7.2 ± 0.6 μmol/mL, respectively.

The basal rate of urea turnover was 6.4 ± 1.2 μmol/kg/min, and during VOLT infusion the value was 6.2 ± 1.1 μmol/kg/min (NS) (Fig. 4).

Dipyridamole Infusion

Dipyridamole (PERS) infusion did not result in any change in either the plasma glucose concentration or in the rate of glucose appearance. The basal values for plasma glucose concentration, glucose rate of appearance, and plasma glucose clearance were 8.1 ± 1.1 μmol/mL, 15.5 ± 1.1 μmol/kg/min, and 1.8 ± 0.2 mL/kg/min, respectively.

VOLT infusion did not significantly alter the rate of FFA appearance or the rate of urea appearance. The basal rate of FFA appearance was 8.1 ± 3.6 μmol/kg/min, and during VOLT infusion the value was 7.9 ± 2.0 μmol/kg/min. The basal rate of urea turnover was 8.2 ± 1.8 μmol/kg/min, and during VOLT infusion the value was 8.4 ± 2.0 μmol/kg/min (NS) (Fig. 4).

Discussion

In a general sense, our study highlights the complexity of the processes involved in the regulation of metabolism in severely ill surgical patients; despite the fact that our study has outlined the importance of a number of regulatory mechanisms, we have probably only scratched the surface, and a host of other regulatory processes are also of importance.

The somatostatin studies allowed us to differentiate between the effects of a variety of hormones. The infusion of somatostatin alone resulted in a significant suppression in the plasma levels of insulin, glucagon, and HGH, and this was associated with a significant decrease in the rate of net protein loss both in the basal state and in the patients who were established on TPN. The decrease in insulin availability would not have promoted this decrease in protein loss since insulin is known to be a potent anabolic hormone.[13,14] A decrease in HGH availability probably would also not have promoted this decrease in NPC since Mason and Wilmore[40] have recently shown that the infusion of HGH is associated with an improvement in protein balance, and cortisol could not have been responsible since the plasma cortisol level did not change significantly following somatastin infusion. We have previously shown that glucagon is important in the mediation of the metabolic response to stress in septic animals,[16] and in the present study the decrease in NPC following somatostatin infusion was associated with a significant decrease in the plasma glucagon concentration. Our data are also consistent with a number of animal studies (*e.g.*, Salter et al.[41]) that have shown that glucagon promotes protein catabolism *in vitro*. The failure of somatostatin infusion alone to induce any change in glucose kinetics is probably explained by the changes in the insulin:glucagon (I:G) ratio that occurred following somatostatin infusion. In the basal state the I:G ratio was 0.1 and when somatostatin was infused this decreased to 0.02. This response would have favored an increase in glucose turnover,[41] but, on the other hand, this effect would have been opposed by the decrease in the HGH level since HGH is known to promote glucose production.[40] When somatostatin was infused and a state of hyperinsulinemia maintained, in contrast to what was seen during somatostatin infusion alone, the I:G ratio increased from 0.08 to 0.2, and this was associated with a significant decrease in glucose turnover and, consequently, in glucose clearance. The role of insulin infusion in the regulation of net protein loss appeared to be relatively minor in the patients we studied since the degree of protein sparing that followed somatostatin infusion was of similar magnitude irrespective of whether or not insulin was also infused.

The effect of ranitidine infusion was similar to that of somatostatin: no change in glucose kinetics and a significant decrease in the rate of protein loss both in the basal state and during TPN. Again, as with somatostatin infusion the protein sparing effect of ranitidine infusion was independent of both insulin and cortisol, and the degree of effect was similar in the three groups assessed. It is not possible to determine from our study whether the effect of the ranitidine infusion on protein loss was via a H_2 type blockade or via another mechanism. The dose of ranitidine we used is known to be effective in inducing H_2 blockade of the parietal cell mass in severely ill surgical patients,[42] and histamine blocking agents are known to minimize the metabolic effects of experimental septic shock in animals,[18] an effect thought to be mediated via the histamine receptor system. On this basis, it is likely that the effect of ranitidine to reduce protein loss in these patients was via the blockade of histamine type 2 receptors, although specific experiments would be required to prove this.

The fact that neither of the prostaglandin inhibitors resulted in any significant decrease in protein loss is in contrast with what we predicted would happen from available animal data. *In vitro* studies have shown that in general terms the prostaglandin system is involved in the promotion of muscle catabolism, and, on this basis, it appeared likely that the infusion of agents known to be prostaglandin antagonists would result in a decrease in protein loss in the patients we studied. It is possible that the agents we employed did not antagonize the specific

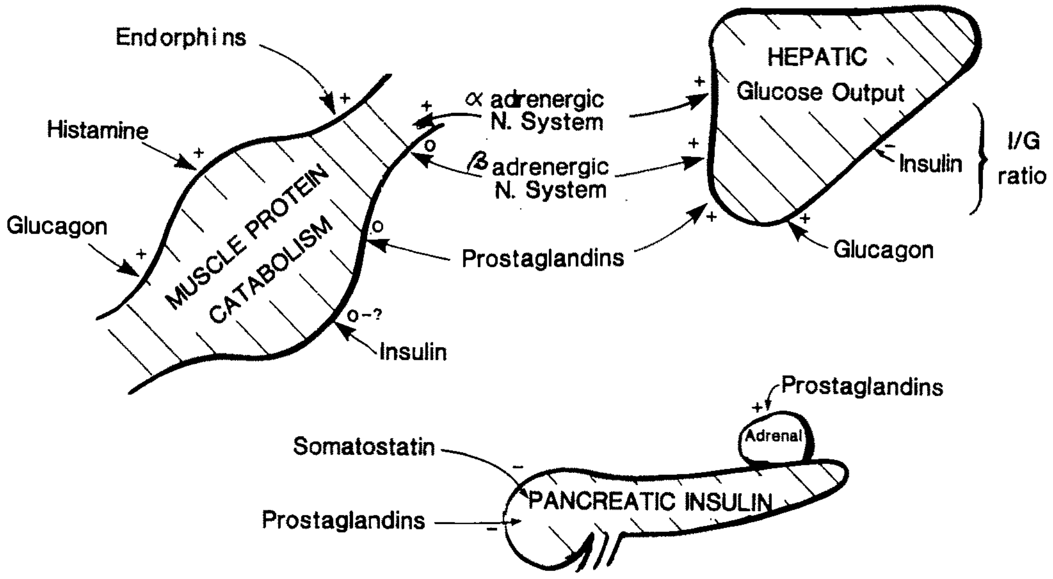

FIG. 5. An integrated assessment of the roles of glucagon, insulin, endorphins, the adrenergic nervous system, and prostaglandins in the regulation of muscle and liver metabolism. + = stimulatory effect; − = inhibitory effect; 0–? = no effect or possible effect; I/G ratio = insulin/glucagon ratio; N. System = nervous system.

prostaglandins responsible for the promotion of muscle catabolism, or, alternatively, that there was an inhibition of the activity of both the inhibitory and stimulatory prostaglandins (with respect to protein breakdown). Our findings agree with those of others who were also unable to demonstrate a protein sparing effect of prostaglandin blockade *in vivo.*[43] The prostaglandin blocking agents did, however, have a number of hormonal effects. The infusion of either agent resulted in an increase in the plasma insulin level ($p < 0.05$ in the case of diclofenac), and in both cases this change in the plasma insulin level was associated with a decrease in glucose turnover ($p < 0.05$ in the diclofenac group). Despite these increases in the plasma insulin level and in the dipyridamole group and associated significant decrease in the plasma cortisol level, there was no effect on protein sparing. This was surprising since both of these hormonal responses would have been expected to favor protein conservation.[13,14]

Naloxone has been shown to improve survival in animals subjected to experimental septic shock[19] via an inhibition of endorphin availability. Our study failed to show any effect of naloxone on glucose turnover, or on the levels of insulin, cortisol, or FFA. However, the infusion of naloxone was associated with a small but statistically significant decrease in protein loss. This finding is consistent with the animal data of Holaday and Faden[19] who found that naloxone minimized the metabolic changes induced by endotoxemia. It is likely that the same mechanism was involved in the patients we studied, but this is not conclusively proved in our study and specific experiments would be required to elucidate this.

We have previously shown that fat is a preferred energy source both in severely ill animals and in severely ill surgical patients.[26–28] In addition, the promotion of lipolysis is a beta-adrenergic effect[15] that is inhibited by beta-adrenergic blockade and promoted by beta-adrenergic stimulation.[15] On this basis, we thought it was likely that the promotion of the availability of a preferred energy substrate (FFA) would possibly exert a protein sparing effect. Our study showed that beta stimulation with salbutamol resulted in an increase in FFA turnover, but there was also an increase in alanine appearance in the plasma, presumably arising from muscle catabolism.[44] This latter effect would have been expected to have been associated with an increase in catabolism and, therefore, in urea rate of appearance, but this was not seen. We have previously shown that changes in alanine rate of appearance and changes in urea turnover do not always go hand in hand (*e.g.,* during glucose infusion[33]), and this present observation appears to be another such example. Thus, although the promotion of lipolysis would probably be a desirable effect in these patients, beta-adrenergic stimulation was not associated with a conservation of protein; rather the release of alanine (presumably from muscle) actually increased.

By integrating the data from the various protocols in this series of studies it is possible to develop a model of the regulation of energy and protein metabolism in severely ill patients. This is summarized in Figure 5.

In summary, our study shows the following: (1) Somatostatin infusion and ranitidine infusion both result in a small but significant decrease in the rate of protein loss in severely ill surgical patients, both in the basal state and during TPN. The primary mechanism is via a decrease in WBPC, and in the TPN patients this is a particularly important response since we have previously shown that the use of TPN alone does not result in a suppression of the elevated rate of WBPC usually seen in severely ill surgical patients,[3,4] the protein sparing effect being purely due to a promotion of WBPS. (2) The infusion of the prostaglandin blocking agents dipyridamole and diclofenac induced changes in serum hormonal levels and changes in glucose kinetics, but neither agent resulted in any conservation of protein. (3) Beta-adrenergic stimulation with salbutamol induces an increase in FFA availability, but there is no decrease in the rate of net protein loss following the infusion of this agent, and the rate of appearance of alanine into the plasma actually increases. (4) Naloxone infusion does not result in any significant change in either plasma insulin or cortisol levels or in glucose kinetics, but there is a small but significant decrease in the rate of net protein loss. As is the case with somatostatin and ranitidine, this effect appears to be via a decrease in WBPC. (5) Despite the fact that the magnitude of the changes in protein loss following the use of these agents is small with the dosages used, the use of combined agents or higher doses of individual agents might conceivably produce a more pronounced effect.

Energy and Protein Metabolism in Sarcoma Patients

JAMES H. F. SHAW, M.D., F.R.A.C.S.,* DAVID M. HUMBERSTONE, M.B.,* and ROBERT R. WOLFE, PH.D.†

From the University Department of Surgery, Auckland Hospital, Auckland, New Zealand, and the Metabolic Research Unit, University of Texas, Medical Branch, Galveston, Texas†*

We have performed a series of isotopic infusions both in normal volunteers (N = 16) and in sarcoma patients (N = 7). Using the primed-constant infusion of stable or radioisotopes we have determined the rates of glucose turnover, glucose oxidation, glucose recycling, and net protein catabolism (NPC). In addition, we have measured VO_2 and VCO_2. The values for VCO_2 and VO_2 were higher in the patients than in the volunteers (mean VO_2 values in volunteers and patients: 107 ± 13 and 158 ± 13 μmol/kg/min, respectively). The basal rate of glucose appearance in the sarcoma patients was twice the value seen in the volunteers (28.3 ± 3.5 *vs.* 13.9 ± 0.3 μmol/kg/min). Glucose infusion in the volunteers resulted in virtually total suppression of endogenous glucose production, while in the patients glucose infusion induced only a 30% suppression of endogenous glucose production ($p < 0.01$). The rate of glucose clearance in the patients was approximately twice the value seen in the volunteers [5.4 ± 1.0 *vs.* 2.7 ± 0.1 mL/kg/min ($p < 0.01$)]. The per cent of glucose uptake oxidized in the patients was significantly less than in the volunteers [22% *vs.* 36% ($p < 0.05$)], and the per cent of glucose uptake that was recycled was significantly higher in the patients [55% *vs.* 10% ($p < 0.01$)]. In addition, the basal rate of net protein loss was increased twofold in the patients [3.2 ± 0.5 *vs.* 1.4 ± 0.4 g (protein)/kg/d ($p < 0.01$)], and in contrast to the situation in the volunteers there was no suppression in the rate of net protein loss when the patients were infused with glucose. The basal insulin concentration and the insulin response to glucose infusion in the patients were similar to that of the volunteers, but the plasma cortisol level was similar in volunteers and in the patients ($p < 0.05$). We conclude from these studies the following: (1) Sarcoma patients have significantly elevated rates of glucose production and glucose clearance, but they have an impaired capacity to directly oxidize either endogenous or infused glucose, coupled with an increased rate of glucose recycling. (2) Sarcoma patients have an elevated metabolic rate and are catabolic. In addition, in contrast with normal volunteers, glucose infusion does not result in a suppression of protein loss.

ENERGY AND PROTEIN METABOLISM in cancer patients has been widely studied by a number of investigators.[1–4] In a general sense, it is clear that there is a metabolic reaction of the host in response to the presence of a malignant tumour, especially if there is advanced disease.[2] However, it is difficult to formulate a clear picture regarding the specific details of the individual metabolic changes that occur in response to particular types of cancer.

A number of studies addressing the metabolic response to tumour bearing have not accounted for the possible variations in metabolic response that might exist between patients with cancers of different histologic type.[5] A number of investigators have shown that there are substantial metabolic differences depending on the anatomic site and histologic type of the cancer. Buzby et al.,[4] for example, have shown that pancreatic cancer patients have low metabolic rates whereas patients with lung cancer or malignant lymphoma tend to have high metabolic rates. We have previously shown that patients with lower gastrointestinal (GI) cancer are metabolically similar to normal volunteers, while patients with upper GI cancer have elevated rates of lipolysis, glucose turnover, and an increased reliance on glucose as an energy substrate.[5,6] In addition, we have demonstrated that patients with advanced head and neck cancer are also metabolically abnormal, having accelerated rates of glucose turnover, glucose recycling, and a loss of the protein-sparing response to starvation.[7]

In a general sense, based on available data in the literature (mainly from animals), it appears likely that sar-

TABLE 1. *Clinical Detals of Patients*

Patient No.	Age	Sex	Diagnosis and Stage of Disease	% Weight Loss†
1	21	M	Osteogenic sarcoma femur, lung METS*	<5
2	67	M	Retroperitoneal MFH, no METS	8
3	76	M	Liposarcoma thigh, no METS	0
4	17	M	Osteogenic sarcoma thigh, lung METS*	<5
5	80	F	Retroperitoneal liposarcoma, no METS	20
6	71	F	Liposarcoma forearm, no METS	0
7	80	F	Anaplastic neuroendocrine sarcoma scalp, lung METS	10

* Primary lesion had been resected previously.

† % weight loss was estimated on the basis of previous well weight.

METS = metastatic disease present.

MFH = malignant fibrous histiocytoma.

Patient nos. 2, 3, and 5 had bulky disease (tumour bulk >0.5 kg) Patient nos. 1 and 4 had previously had bulky primary disease, but at the time of study the only known disease was multiple bilateral lung metastases in both cases. Patient no. 6 had a small primary lesion weighing <150 g. Patient no. 7 had 150 g of primary tumor, 150 g of tumor in neck nodes, and bilateral pulmonary metastases.

coma patients probably display a number of metabolic abnormalities, and they may also differ from GI cancer patients or head and neck cancer patients. Brennan et al.[8] have shown that sarcoma-bearing animals have high metabolic rates, high rates of glucose turnover,[9] high rates of glucose recycling,[10] and enhanced rates of both protein synthesis and degradation.[11] In addition, Norton et al.[12] have shown that sarcoma patients are glucose intolerant.

In view of the fact that (1) sarcoma patients do not infrequently require nutritional support as an adjunct to what is often aggressive anticancer therapy and (2) very few metabolic studies have been performed in sarcoma patients, we have performed a series of studies to address a number of aspects of energy and protein metabolism in a group of sarcoma patients. In particular, we have used isotopic tracer methodology to measure rates of glucose turnover, glucose oxidation, and net protein catabolism (NPC) both in the basal state and during glucose infusion. In addition, we have estimated plasma insulin and cortisol values, and have determined rates of oxygen consumption and CO_2 production. The responses seen in the sarcoma patients have been compared with similar data obtained in a group of normal volunteers.

Materials and Methods

Studies were performed in 16 normal volunteers, and in seven sarcoma patients. In all instances the patients (all volunteers) were at least 12 hours postabsorptive at the time of study.

The study was approved by the institutional board at Auckland Hospital, and the use of radioisotopes was approved by the National Radiation Laboratory (New Zealand). The clinical details of the patients are summarized in Table 1.

Experimental Protocol

All experiments involved the infusion of isotopes and the collection of blood samples. The experiments each consisted of two periods (periods 1 and 2). At the start of period 1 a primed-constant infusion of isotopes was started and maintained for the duration of the study. In the volunteers period 1 lasted for 120 minutes, and blood samples for isotopic enrichment measurements were taken during the last 30 minutes. In the patients period 1 lasted for 180 minutes and blood samples were taken over the last 60 minutes. During the 120 minutes of period 2, in both the patients and volunteers the isotopic infusion was continued, and in addition glucose was infused at approximately 4 mg/kg/min. Blood samples were taken again during period 2. In addition, ten infusions were performed where there was no perturbation in period 2. Isotopes alone were infused throughout.

Isotopic Infusions and Calculations

In the volunteers only stable isotopes were employed, while in the patients a combination of stable and radioisotopes was used.

Glucose kinetics were determined using the primed-constant infusion of either 6,6 D2-glucose or 6-^{3}H-glucose as we have described before,[13] and glucose oxidation was measured using the primed-constant infusion of either ^{14}C-glucose or ^{13}C-glucose and appropriate priming of the bicarbonate pool.[13–15]

The primed-constant infusion of 15N-urea was used to determine urea rate of appearance in the volunteers, and in the patients similar methodology was employed using either ^{14}C- or 15N-urea. We have described this methodology previously.[13,16–19] Rates of NPC were calculated from the urea data.

Rate of appearance was calculated using the Steele equation[20] in the case of radioisotopes, and for 15N-, D2- and ^{13}C-labeled tracers the Steele equation was modified appropriately.[15–19]

Rates of NPC were calculated from the urea appearance data.[13,17,18,21]

We have previously shown that the primed-constant infusion of either ^{14}C-urea or 15N-urea to estimate urea

TABLE 2. *Metabolic Profiles of Volunteers Depleted Patients, and Cancer Patients*

	VOL	DEP	ELGI	AUGI	SARC
Glucose production (μmol/kg/min)	14 ± 1	16 ± 2	13 ± 1	18 ± 1*	28 ± 4*
Glucose clearance (mL/kg/min)	2.7 ± 0.1	3.1 ± 0.3	2.7 ± 0.3	3.4 ± 0.2*	5.4 ± 1.0*
% glucose uptake oxidized	36 ± 2	35 ± 19	38 ± 2	48 ± 6*	22 ± 2*
% glucose uptake recycled	10 ± 1	35 ± 25	6 ± 2	11 ± 5	56 ± 5*
NPC (g/kg/d)	1.4 ± 0.4	0.8 ± 0.1*	1.3 ± 0.3	2.1 ± 0.2*	3.2 ± 0.7*

* Significantly different from corresponding VOL value ($p < 0.05$ or better).

VOL = volunteers.

DEP = seven patients with depletion as a result of benign disease (peptic ulcer disease in five and inflammatory bowel disease in two).[36]

ELGI = early localized lower GI cancer.[5,6,36]

AUGI = advanced upper GI cancer.[5,6,36]

SARC = sarcoma patients.

rate of appearance in the plasma produces similar results,[16] and also that the rates of glucose appearance in plasma calculated using the primed-constant infusion of ^{14}C-glucose and ^{13}C-glucose administered simultaneously are virtually identical.[15] In addition, the rate of glucose appearance determined in volunteers using 6,6 D2-glucose is virtually identical to the value determined in nonstressed ward patients with benign peptic ulcer disease using 6-^{3}H-glucose (Table 2).

Statistical Analyses

Because there were no significant changes in either kinetic or hormonal levels between periods 1 and 2 in the control studies, the data obtained in period 2 of each study were compared with the corresponding period 1 data using a paired t-test. In addition, the data obtained in the various groups were compared using ANOVA.

Calorimetry

Rates of oxygen consumption and CO_2 production were measured using a Sybron Taylor O_2 analyzer and an ADC (Herts, England) CO_2 analyzer, as we have described previously.[13,18]

Analysis of Samples

Blood samples were immediately chilled and later centrifuged to separate the plasma.

Plasma glucose specific activity, plasma glucose enrichment, and expired air CO_2 enrichment, and/or specific activity were determined as described elsewhere.[13,15,17,19]

We have previously described the methods by which plasma ^{14}C-urea-specific activity[13,16,18] and plasma 15N-urea enrichment[16] were determined.

Serum levels of insulin and cortisol were determined by radioimmunoassay.[22,23]

Results

Calorimetry

The values for VO_2 and VCO_2 were higher in the patients than in the volunteers. The mean value of VO_2 in the volunteers was 107 ± 8 μmol/kg/min, and in the patients the corresponding value was 158 ± 12 μmol/kg/min. The basal values for VCO_2 in volunteers and patients were 80 ± 12 and 114 ± 9 μmol/kg/min, respectively ($p < 0.05$). The basal RQ in the volunteers was 0.76 ± 0.4, and in the sarcoma patients the value was similar (0.74 ± 0.4).

Insulin and Cortisol Levels

The basal cortisol concentration in the sarcoma patients was 495 ± 55 pmol/L, which was not significantly different from the locally determined value in normal humans. The basal insulin level in the patients was 7 ± 1 mIU/L and during glucose infusion this increased significantly ($p < 0.01$) to 27 ± 3 mIU/L. The basal insulin level in the volunteers was 11 ± 3 mIU/L and during glucose infusion the magnitude of the insulin response was similar to that seen in the patients. The period 2 value in the volunteers was 22 ± 7 mIU/L.

Glucose Kinetics

The basal glucose concentrations in the volunteer (VOL) group and in the patients were similar (5.2 ± 0.1 and 5.4 ± 0.3 μmol/mL, respectively). During glucose infusion the plasma glucose concentration rose significantly in both volunteers and patients ($p < 0.01$). The respective values for volunteers and patients were 7.5 ± 0.3 and 8.3 ± 0.5 μmol/mL (Fig. 1).

The basal rate of glucose appearance in the plasma in the VOL group was 13.9 ± 0.3 μmol/kg/min, and during glucose infusion there was near total suppression of endogenous glucose production. In the VOL group the rate of glucose production during glucose infusion was 0.8 ± 0.5 μmol/kg/min, and this represented a 96% suppression of endogenous glucose production. In contrast, the basal rate of glucose turnover in the sarcoma patients was significantly elevated ($p < 0.01$). The basal value for the glucose rate of appearance in the patients was 28.3 ± 3.5 μmol/kg/min and during glucose infusion there was significantly smaller suppression of endogenous glucose production ($p < 0.01$). During glucose infusion in the sarcoma patients the rate of endogenous

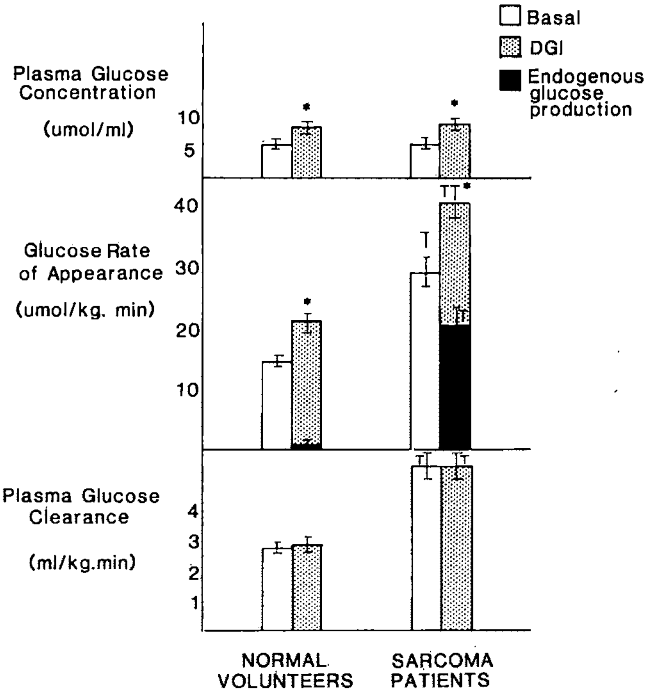

FIG. 1. Glucose kinetics in volunteers and sarcoma patients, and the response to glucose infusion. Values are given as mean ± SEM. DGI = during glucose infusion (4 mg/kg min). * Significantly different from basal value ($p < 0.01$). T, significantly different from equivalent volunteer value ($p < 0.05$).

glucose production was 20.8 ± 2.9 μmol/kg/min [significantly different from the corresponding VOL value ($p < 0.01$)]. The per cent suppression of endogenous glucose turnover in the patients was 32 ± 5 [significantly different from the VOL value ($p < 0.01$)] (Fig. 1).

The basal rate of glucose clearance in the volunteers was 2.7 ± 0.1 mL/kg/min and during glucose infusion the value was 2.8 ± 0.2 mL/kg/min. The rate of glucose clearance in the sarcoma patients was significantly greater than the corresponding VOL value, both in the basal state and during glucose infusion ($p < 0.01$). The period 1 and 2 values for glucose clearance in the patients were 5.4 ± 1.0 and 5.4 ± 1.1 mL/kg/min, respectively (Fig. 1).

The basal rate of glucose oxidation in the volunteers was 5.1 ± 0.3 μmol/kg/min, and during glucose infusion this increased to 7.2 ± 0.6 μmol/kg/min ($p < 0.01$). The rates of glucose oxidation in the sarcoma patients were higher than in the volunteers. The basal rate of glucose oxidation in the patients was 6.4 ± 0.9 μmol/kg/min and during glucose infusion the value was 9.0 ± 0.8 μmol/kg/min.

The per cent of the total VCO_2 derived from glucose oxidation in the VOL group was 25 + 3 in the basal state, and during glucose infusion 37 ± 2% of the total VCO_2 was derived from glucose oxidation ($p < 0.05$). In the patients 32 ± 2% of the total VCO_2 was derived from glucose oxidation; and during glucose infusion the value was 45 + 4%.

The per cent of glucose uptake oxidized in the VOL group in the basal state was 36 ± 2, and during glucose infusion the value was 36 ± 3%. The corresponding values for per cent glucose uptake oxidized in the sarcoma patients were significantly lower ($p < 0.05$). The period 1 and 2 values were 22 ± 2% and 20 ± 2%, respectively (Fig. 2).

The basal rate of glucose recycling in the volunteers was 10 ± 1%, and during glucose infusion this value increased to 21 ± 3%. In the sarcoma patients the basal value of glucose recycling was 56 ± 5%, and during glucose infusion the value was 55 ± 5%. These values in the patients were significantly higher than the VOL values ($p < 0.05$).

In the VOL group the basal value for urea rate of appearance was 5.7 ± 0.7 μmol/kg/min, and during glucose infusion this decreased significantly ($p < 0.02$) to 4.99 ± 0.89 μmol/kg/min. The basal value for urea rate of appearance in the sarcoma patients was significantly higher ($p < 0.01$), and in contrast to what was seen in the VOL group glucose infusion did not result in any significant suppression. The basal value in the patients was 12.6 ± 2.7 μmol/kg/min, and during glucose infusion the value was 11.9 ± 2.5 μmol/kg/min. The values for

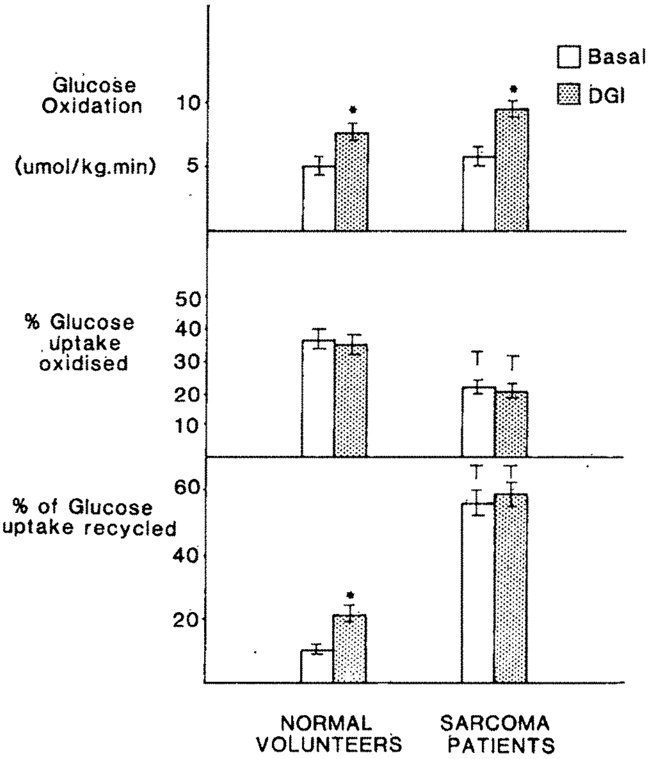

FIG. 2. Rates of glucose oxidation and glucose recycling in volunteers and patients, and the response to glucose infusion. Values are given as mean ± SEM. * Significantly greater than corresponding period 1 value ($p < 0.05$). T, significantly different from equivalent volunteer value ($p < 0.05$). DGI = during glucose infusion.

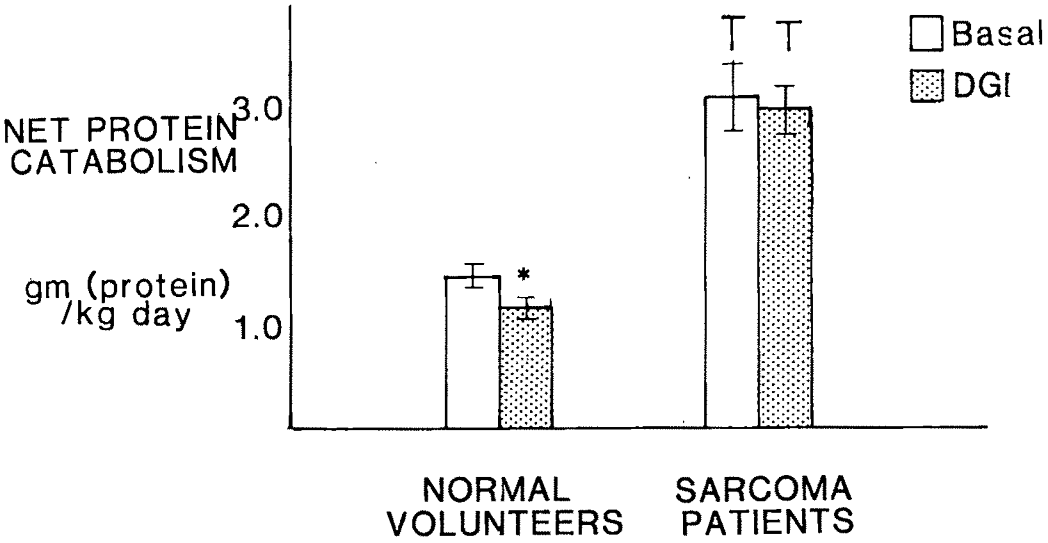

FIG. 3. NPC values in volunteers and sarcoma patients, and the response to glucose infusion. Values are given as mean ± SEM. DGI = during glucose infusion. * Significant decrease compared with basal value ($p < 0.02$). T, significantly greater than corresponding volunteer value ($p < 0.05$).

net protein breakdown were calculated from the urea turnover data. In the VOL group the values for period 1 and 2 were 1.44 ± 0.18 and 1.26 ± 0.22 g (protein)/kg/d. The corresponding values in the sarcoma patients were 3.18 ± 0.68 and 3.00 ± 0.63 g (protein)/kg/d, respectively (Fig. 3).

Discussion

In a general sense, our study confirms in the sarcoma patient a number of the abnormal findings other investigators have documented in sarcoma-bearing animals.[8-11] In addition, the extent of the metabolic derangement seen in these patients is impressive and as great in magnitude as those we have previously described in surgical patients with either trauma, sepsis, or pancreatitis.[5,6,13,17,18,24]

The mean basal value for glucose rate of appearance in the sarcoma patients (over 28 μmol/kg/min) was twice the value seen in the volunteer group (approximately 14 μmol/kg/min). In addition, this rate of glucose turnover is higher than the values we have previously described in either severe sepsis[17,25] or in pancreatitis.[13] Furthermore, the minimal suppression of endogenous glucose turnover seen in these patients during glucose infusion (30% suppression in the patients *vs.* near total suppression in the volunteers) is less than that seen in patients with GI cancer,[5] and closely resembles what is seen in critically ill patients with either sepsis[17,25] or pancreatitis.[13]

This observation of an increased rate of glucose production in sarcoma patients is in accord with the observations of a number of investigators in sarcoma-bearing animals. For example, Arbeit et al.[9] found that sarcoma-bearing rats had higher rates of glucose turnover than non–tumor-bearing rats, and Roh et al.[10] have reported that hepatocytes isolated from sarcoma-bearing rats have a significantly elevated gluconeogenic capacity and an accelerated rate of alanine transport in comparison to what was seen in hepatocytes from control animals.

The increased basal rate of oxygen consumption in the sarcoma patients is consistent with available animal data. For example, Lindmark et al.[26] observed that sarcoma-bearing mice had significantly higher rates of energy expenditure, and Roh et al.[8] have shown that hepatocytes isolated from sarcoma-bearing rats have significantly elevated rates of oxygen consumption compared with hepatocytes from control animals. Our study also provides information regarding the utilization of individual substrates in the sarcoma patients. The basal RQ in the patients was 0.74, while in the VOL group the value was 0.76. When the rate of fat oxidation is estimated from the calorimetry and NPC data using standard equations,[27] the rate of fat oxidation in the patients is 0.65 mg/kg/min *versus* 0.84 mg/kg/min in the VOL group. This lower rate of fat oxidation in the patients (compared with the VOL group), combined with the impaired capacity of the sarcoma patients to directly oxidize glucose to CO_2, indicates that the two major differences in terms of energy metabolism in the sarcoma patients were (1) an increased reliance on protein breakdown (the rate of NPC in the patients was more than twice the value determined in the VOL group), and (2) an increase in the anaerobic metabolism of glucose.

The percentage of glucose uptake that was oxidized in the patients was significantly lower than in the VOL group, and the percentage of glucose appearing in the plasma that was recycled in the patients was significantly higher. In the VOL group approximately 36% of the glucose uptake was oxidized, and 10% of the glucose appearing in the plasma was recycled, while in the patients only 22% of the glucose uptake was oxidized and 55% of the glucose appearing in the plasma was recycled.

TABLE 3. *Summary of the Alterations in Energy and Protein Metabolism Seen in Sarcoma Patients*

Basal glucose rate of appearance	Increased 100%
Plasma glucose clearance (basal and DGI)	Increased 100%
% glucose uptake oxidized (basal and DGI)	Decreased 40%
Rate of glucose recycling	
Basal	Increased 500%
DGI	Increased 250%
Metabolic rate	Increased 35%
NPC	
Basal	Increased 100%
DGI	Increased >100%
Basal plasma cortisol level	Not altered
Basal plasma insulin level and insulin response to DGI	Not altered
Suppression of endogenous glucose turnover DGI	Decreased 70%
Suppression of protein loss DGI	No suppression

The alterations are expressed as a comparison with the normal volunteer data.
DGI = during glucose infusion.

Thus, the liver of the sarcoma patient is apparently stimulated to provide a large amount of glucose, some of which is used by the tumor via anaerobic glycolysis, with lactate being recycled to the liver. This high rate of glucose recycling in the sarcoma patients is consistent with what has been documented by a variety of investigators in patients with many different types of malignant disease. For example, Cori and Cori[28] and Warburg et al.[29] demonstrated the importance of anaerobic glucose metabolism in the substrate economy of tumors in the 1920s, and more recently Waterhouse et al.[30] have demonstrated high rates of lactate turnover in patients with advanced cancer. In addition, Roh et al.[10] have shown that hepatocytes isolated from sarcoma-bearing rats have significantly elevated rates of gluconeogenesis from lactate compared with hepatocytes from control animals.

The sarcoma patients were catabolic compared with the volunteers; the basal rate of NPC in the patients was more than twice the value seen in the volunteers [approximately 3.2 *vs.* 1.4 g (protein)/kg/d]. In addition, in contrast to what was seen in the volunteers, glucose infusion did not result in any significant decrease in catabolism. This latter aspect of the response is similar to what we have previously described in patients with advanced GI cancer: an increase in NPC and no suppression following either glucose infusion[5] or isocaloric lipid infusion.[31] A number of others have documented catabolism in animal sarcoma models. Warren et al.[11] have shown that hepatocytes from sarcoma-bearing rats have significantly elevated rates of both hepatic protein synthesis and hepatic protein catabolism in comparison to controls. *In vivo* studies in animals also indicate that sarcoma-bearing is associated with catabolism. Norton et al.[32] have shown that sarcoma-bearing rats have significantly elevated rates of whole body protein catabolism, and Karlberg et al.[33] have demonstrated that sarcoma-bearing rats are in negative nitrogen balance compared with controls due to an enhanced rate of protein catabolism.

The basal insulin levels in the volunteers and patients were similar in our study, and the insulin response to glucose infusion was of similar magnitude in the two groups. These findings are in general agreement with those of Norton et al.[12] In a group of 27 sarcoma patients they found that basal insulin and glucagon levels were not significantly different from equivalent measurements in control subjects. In addition, the sarcoma patients in our study had plasma cortisol levels that were similar to those of volunteers. Thus, although cortisol is known to promote protein breakdown, induce an increase in glucose turnover, and promote substrate recycling,[34,35] it was probably not cortisol that was responsible for these changes in the sarcoma patients.

Why the sarcoma patients are so metabolically abnormal compared with volunteers, or with patients with localized lower GI cancer[5,6,36] is not completely explained by our study. It is clear, however, that sarcoma patients are more like weight-losing upper GI cancer patients in that they also have increased rates of glucose production, increased glucose clearance, increased NPC, and minimal conservation of host tissue following glucose infusion.[5,6,36] A factor common to both weight-losing GI cancer patients and sarcoma patients is the increased rate of glucose production coupled with an increased rate of glucose degradation. In the GI cancer patients this increased glucose degradation is due to an increase in aerobic glucose oxidation, while in the sarcoma patients there is an anaerobic glycolysis. When these data are considered in conjunction with the decreased rate of fat utilization seen in these two groups of patients,[6,36] it appears that a major effect of tumour bearing in these two types of cancer is the consumption of host tissue in order to meet an increased need for glucose, presumably due to increased utilization by the cancer per se either aerobically or anaerobically.[28]

These metabolic effects are clearly different from those described in simple starvation,[37] where the major changes involve a decreased reliance on glucose for energy, an increased reliance on fat, and a conservation of protein rather than an increase in protein loss as seen in weight-losing cancer. In view of the fact that we have studied a group of patients suffering from depletion as a result of benign GI disease,[36] we have compared the metabolic effects of depletion as a result of benign disease with the metabolic profile of the sarcoma patients. [We have also included the metabolic profile of the GI cancer patients for comparative purposes (Table 2)]. When these various groups of cancer patients are compared with each other, and with patients suffering from pure depletion, it is apparent that metabolically cancer patients are different from depleted patients, and that the metabolic response to tumour bearing is not uniform, but rather dependent on stage of disease, degree of weight loss, and anatomic site.

In summary, our study demonstrates that sarcoma patients display the following metabolic abnormalities in comparison to what is seen in normal volunteers: (1) an increase in metabolic rate of approximately 35%; (2) a significant increase in both glucose turnover and plasma glucose clearance; (3) the direct oxidation of glucose to CO_2 is impaired, and this is coupled with a significant increase in glucose recycling; (4) sarcoma patients have a significantly elevated rate of NPC; and (5) in contrast to what is seen in normal volunteers, sarcoma patients have a diminished capacity to conserve host resources when infused with glucose. There is no significant suppression of the elevated rate of net protein breakdown and there is less suppression of the consumption of host tissue for gluconeogenesis.

The differences between sarcoma patients and normal volunteers are summarized in Table 3, and in Table 2 the metabolic profiles of volunteers, depleted patients, and GI cancer patients are compared.

Acknowledgments

The authors gratefully acknowledge assistance from the medical and nursing staff of the Professorial Unit surgical wards at Auckland Hospital. We are also grateful to Ms. Andrea Gardner, Ms. Heather Third, and Ms. Mavis McCombie for technical help, and Mrs. Marta Wolfe for performing the mass spectroscopy analyses.

Weight Loss with Physiologic Impairment

A Basic Indicator of Surgical Risk

JOHN A. WINDSOR, M.B., and GRAHAM L. HILL, M.D., F.R.A.C.S.

It is a long held belief that weight loss is a basic indicator of surgical risk. Many experienced surgeons, however, think otherwise. We have investigated the proposition that weight loss is a risk factor for postoperative complications but only when associated with clinically obvious physiologic impairment. Before major surgery, 102 patients had a careful history taken to ascertain if there had been recent weight loss and a reduction in the capacity for activity. Physical examination included assessment of mood, skeletal muscle function, respiratory muscle function, and wound healing. Plasma albumin was also measured. Using this information the patients were placed into one of three groups. Group I (N = 43) were normal, group II (N = 17) had weight loss > 10% but no clinical evidence of physiologic impairment, and group III (N = 42) had weight loss > 10% with clear evidence of dysfunction of two or more organ systems. The patients in group III had significantly more postoperative complications ($p < 0.05$). They also had more septic complications ($p < 0.02$) including a higher incidence of pneumonia ($p < 0.05$) and a longer hospital stay ($p < 0.05$) than patients in each of the other two groups. Objective measurements of body stores of protein and liver, and psychologic, respiratory, and skeletal muscle function, confirmed the validity of the clinical classification into the risk groups. The results demonstrate that weight loss is a basic indicator of surgical risk in modern practice providing it is associated with clinically obvious impairment of organ function. They suggest that adequate body protein stores are necessary for normal body function and for minimizing the risks of surgery.

From the Department of Surgery, University of Auckland School of Medicine, Auckland, New Zealand

IN 1936 an American surgeon, Hiram Studley, claimed that "weight loss was a basic indicator of surgical risk."[1] In 50 patients undergoing gastric resection for peptic ulcer disease, he showed a striking correlation between preoperative weight loss and postoperative complications.

With advances in surgical practice, including antibiotics, physiotherapy, anesthesia and fluid and electrolyte management, this relationship can no longer be clearly demonstrated. In spite of this, many continue to cite Studley's paper[1] and claim that it proves that protein energy malnutrition is an important risk factor in modern surgery.

In our clinical practice, we have observed that weight loss does not appear to be an important risk factor for postoperative complications, unless it is associated with clinically obvious impairment of physiologic function. Preliminary work suggested to us that patients who are physiologically impaired could be identified by a thorough clinical examination,[2] and because of this we embarked on a formal prospective study to determine whether a clinical assessment of weight loss and physiologic function is able to identify patients with objective evidence of abnormal body composition and function who are also at an increased risk of postoperative complications.

Methods

Patient Selection

From April 1985 to August 1986, all patients presenting to the Department of Surgery at Auckland Hospital for elective surgical procedures, in which a major resection of some part of the gastrointestinal (GI) tract was planned, and for whom preoperative intravenous nutrition (IVN) was not considered essential, were asked if they would be willing to enter this study. On the day before surgery, the 102 patients who agreed to participate in the study underwent a clinical assessment and a series of objective tests to detect the presence of nutritional depletion and physiologic dysfunction.

Clinical Assessment of Weight Loss and Functional Status

Loss of body weight. Weight loss was evaluated from the history and physical examination. A preoperative

weight loss (recalled well weight minus current measured weight)[3] of more than 10% over the preceding 3 months was considered significant.[4] Because there are considerable difficulties in evaluating body weight loss in an individual patient, confirmation was sought by physical examination. On physical examination, confirmation that weight loss had occurred was obtained by palpating several skinfolds and muscle bellies. If there was little or no fat palpable when subscapular, triceps, and biceps skinfolds were palpated, then it was considered that considerable fat had been lost and if on palpation of the bellies of temporalis, supraspinati, biceps, triceps, and interossei muscles revealed considerable losses, then this was taken as further evidence that considerable loss of body protein had occurred.

Functional status. The overall level of physiologic function, both mental and physical, was also assessed on history and examination. Factors that related to an overall reduction in the patient's capacity for activity (including symptoms of tiredness, malaise, depression, and apathy) were particularly looked for.[5] If there had been any major recent changes in the patient's activity level around the home or at work, this was taken as physiologic impairment.[6] Some specific physiologic functions were also assessed as part of the physical examination. To categorize a patient as having an impairment of any of these functions required clear evidence of a significant change within the time period over which the loss of weight had occurred. Psychologic function was assessed by observing the patients' overall mood, taking particular note of the alertness, ability to concentrate, and irritability. Confirmation of exercise intolerance was obtained by observing the patients' general activity level and endurance around the ward.[7] Skeletal muscle function was assessed by having the patient squeeze the examiner's hand, who then determined if the squeeze strength was clearly impaired in the light of the patient's age, sex, and body habitus.[8] Respiratory muscle function was assessed in the context of a full examination of the respiratory system, and particular note was taken of the effort and sound of coughing[9] as well as the presence of shortness of breath. Impairment of the wound healing response was evidenced by unhealed wounds, sores or scratches, and/or the presence of skin sepsis. A serum albumin concentration of less than 32 g/L was also considered a significant impairment.[2]

Categorization of Patients into 3 Groups

The patients were assessed and categorized without knowledge of any objective data, into one of three groups, by a single clinician (J.A.W.): [I] weight loss of less than 10% with no evidence of abnormal physiologic function; [II] weight loss of greater than 10% with no evidence of physiologic dysfunction; and [III] weight loss of greater than 10% with physiologic impairment of at least two of the systems described above (*i.e.*, overall activity level, psychologic function, respiratory function, skeletal muscle function, wound healing, and plasma albumin concentration).

Objective Assessment of Weight Loss and Physiologic Functions

Body composition measurements were made in order to assess the total body fat and protein stores in the three categories of patients. We were also interested in objective data to validate the clinical estimate of physiologic impairment and to this end we measured liver function, skeletal and respiratory muscle function, and psychologic function.

Anthropometry. Skinfold thickness (biceps, triceps, and subscapular) was measured using Holtain skinfold calipers, and body fat was calculated according to the method of Durnin and Wormersly.[10] Midarm circumference (MAMC), an indirect measure of body protein, was calculated as midarm circumference minus triceps skinfold thickness.[11]

Body composition analysis. Prompt *in vivo* neutron activation analysis (IVNAA) and the tritiated water dilution technique were used to measure total body protein (TBP) and total body fat (TBF).[12] The protein index,[13] a measure of protein depletion, is the measured TBP divided by a predicted TBP. The predicted TBP was derived from linear regression equations using the age, height, and sex of a local normal population who had had direct measurements of TBP. In the same way a fat index was calculated from the measured and predicted TBF, and was used to measure the extent of body fat depletion. The fat free mass (FFM) was calculated as the sum of the body water, protein, glycogen, and mineral compartments.[13]

Liver function. Plasma tranferrin and prealbumin were assayed by laser nephalometry.

Skeletal muscle function. Maximum voluntary grip strength was the highest of three values measured by isokinetic dynamometry using the dominant hand. Grip strength was also expressed as a function of the patients' FFM. Using an apparatus based on the principles of Edwards et al.,[14] the relaxation of the adductor pollicis muscle was determined in the unfatigued state after a brief tetanic stimulation (3 seconds) at 50 Hz. The relaxation time was calculated as the time taken for the force of a tetanus to fall 50% of its plateau value.[14]

Respiratory function. Respiratory muscle strength was assessed by measuring mouth pressure with a Validyne bidifferential pressure transducer (Validyne Model MP45, Validyne Engineering Corp., Northridge, CA) during maximal static inspiration (MIP) at functional residual lung capacity and during maximal static expiration (MEP) at total lung capacity.[15] A respiratory muscle strength index was derived as the average of the per cent predicted MIP and MEP. These were derived from regression equations based on the patients' age, height, and sex.[16] Forced expiratory volume in 1 second (FEVI), vital capacity (VC),[17] and peak expiratory flow rate (PEFR) were measured by standard spirometric techniques and were expressed as the percentage and predicted value derived from published regression equations.[18-20]

Psychologic function. Psychologic fatigue was measured using the Profile of Mood Score (POMS) self-questionnaire.[21]

Assessment of Clinical Course after Surgery

The clinical team responsible for each patient's postoperative care was unaware of the results of either the clinical or objective assessments. They diagnosed and recorded the complications independently and determined the date of discharge from hospital according to our usual criteria (patient up and about, eating well, and free of sepsis). The patients were also seen daily by one of us (J.A.W.) who ensured that each postoperative complication was fully documented and diagnosed according to specific clinical and laboratory criteria.

Major complications included intra-abdominal sepsis (proven by culture or abnormal drainage or at reoperation), clinically apparent anastomotic leakages, wound dehiscence (requiring reoperation), proven pulmonary emboli (requiring heparinization), pneumonia (proven by a positive blood and/or sputum culture as well as clinical and radiologic evidence of consolidation; atelectasis excluded), myocardial infarction (proved by ECG changes), cerebrovascular accidents (with neurologic deficit), and any technical problem that required the patient to undergo a further major surgical procedure. Septic complications included intra-abdominal sepsis, pneumonia, septicemia (clinical evidence of systemic infection and two separate positive cultures of the same pathogen in the absence of an obvious focus), wound infection (unequivocal signs of inflammation and a positive culture of a pathogen from the pus exuded from the wound), and urinary infection (greater than 1000 organisms/mL on culture). The number of days from operation to discharge was recorded as were all deaths that occurred within 14 days of the operation.

Statistical Analysis

Quantitative data of the three patient groups were initially evaluated with a one-way ANOVA. Multiple group comparisons of these quantitative data were done using Student's *t*-test incorporating the Bonferroni method, unless it could not be assumed that the results were normally distributed, in which case the nonparametric Kruskal-Wallis test was used.[22] Categorical data, including complication rates, were evaluated using the chi square test with Yates' correction.

Results

Patients in the 3 Clinical Categories

On the basis of the clinical assessment of nutritional and functional status 43 patients were categorized as having insignificant weight loss and normal functional status (group I), 17 patients were categorized as having significant weight loss without significant impairment of physiologic function (group II), and the remaining 42 patients were found to have significant weight loss and physiologic dysfunction as well (group III). Table 1 shows that the group III patients were, on average, older than those in the other two groups. Their average weight was also less. As might be expected, the duration of anesthesia was significantly less in the patients who had significant weight loss. It averaged 2.8 ± 1.4 (SD) hours in groups II and III compared with an average time of 3.7 ± 1.7 (SD) hours in group I $p < 0.05$. The distribution of the types of operative procedures and surgical diagnoses was similar for each of the three categories of patients, with a diagnosis of colorectal cancer in approximately half of the patients, and benign disease of the GI tract in approximately a third.

The Objective Measurement of Fat Stores, Protein Stores, and Physiologic Functions in the 3 Clinical Categories of Patients

Body stores of fat and protein together with objective measurements of function for the three clinical categories of patient are shown in Tables 2 and 3. Although the loss of body weight in groups II and III was similar (13.4% and 14.8%, respectively) and significantly more than that of the patients in group I (3.9%), body composition analysis showed that only the group III patients had body fat and protein stores that were significantly less than group I. The average deficit of body protein for the group II patients was, however, more than 20%. The combined data for the measurements of body protein and body fat in the two nutritionally depleted groups were significantly less than those for body protein (6.8 ± 0.5 kg *vs.* 8.8 ± 0.4 kg, $p < 0.001$) and body fat (13.7 ± 1.6 kg *vs.* 17.3 ± 1.2 kg, $p < .05$) in group I. The fact that there was no significant difference between the patient groups for predicted TBP and TBF indicates that there were no important differences between the groups before illness. The anthropometric measurements of body fat and MAMC confirm the three clinical categories in that groups II and III are significantly different from group I.

The objective tests of physiologic function are shown in Table 3. It is shown that nearly all the indices of liver, skeletal muscle, respiratory, and psychologic function were significantly less in group III patients, confirming that the clinical assessment and categorization of the patients in terms of clinical judgment of physiologic status has some validity.

The Postoperative Course

Table 4 shows that the patients in group III had a significantly higher incidence of major complications, septic complications, and pneumonia. Group III patients also had a longer postoperative hospital stay when compared to group II patients. The incidence of other complications shows a similar trend but does not reach the same level of statistical significance.

Discussion

Fifty years ago Studley suggested that weight loss was a basic indicator of surgical risk.[1] In modern surgical practice this appears to be only partly true since our results have demonstrated that clinically obvious physiologic impairment must be present as well. We have also shown, by sophisticated methodology, that at risk patients, identified through a careful history and examination, have in association with depleted stores of protein and fat, clear evidence of liver, skeletal muscle, and respiratory dysfunction as well as an increased perception of fatigue.

The fat and protein components of weight loss have been separately measured in this study. Preliminary work[23] had suggested to us that marked body protein loss was associated with an increased number of postoperative complications. There is probably a critical extent of body protein loss that must occur before decompensation of vital physiologic functions will result, and this may depend on such factors as the age and physical fitness of the patient, the disease, and the particular physiologic function involved. The category of patients (group III) who had significant physiologic impairment and a higher incidence of complications were signifi-

cantly older, which suggests that such patients have less reserves of functioning body protein. This may account for the well-attested fact that older patients do not withstand major surgery as well as their younger counterparts.

In this study physiologic dysfunction was diagnosed only when weight loss of greater than 10% was also present. The effect on outcome of physiologic dysfunction in the patient group who had not lost this amount of weight might be considered. Only two patients in this category of 43 patients (group I) had significant physiologic dysfunction, and in both cases the dysfunction was related to chronic respiratory disease. One of these patients developed a postoperative pneumonia, while the other had an uneventful postoperative course.

Despite the large number of recommended nutritional assessment techniques (anthropometry, biochemistry, prognostic nutritional indices) that have appeared in the literature over the past 15 years,[24] no risk indicator has been shown to be superior to a careful clinical evaluation of the patient.[2,25] In an earlier study[2] we found that although a surgeon's assessment *from the end of the bed* was able to correctly identify only a small number of very high risk patients, a careful clinical assessment of medical risk, noting in particular cardiorespiratory disease and preexisting sepsis, as well as nutritional state, was as effective as any other currently used indicator of risk. It was suggested by us then that "something more than a global assessment by the operating surgeon is required to identify high risk patients."[2] In our present study we have gone one step further by formalizing a clinical assessment that includes a particular emphasis on the functional effects that are often seen in patients with a significant loss of body weight. This approach can identify a group of patients at high risk of postoperative complications. The skills required for such an assessment are no different than those taught to every student of medicine, and we have found that when the findings are carefully tabulated, interobserver agreement reaches 95% for all patient categories (unpublished observation).

In these times of escalating medical costs, preoperative nutritional repletion in hospital must be shown to be effective. Others have presented prospective data suggesting that a 10-day course of IVN given to all patients prior to major GI cancer surgery is of real benefit.[26] Our work suggests that this approach is excessive and wasteful. It would appear that only those patients who have impairment of important bodily functions in addition to significant loss of body weight should be considered for preoperative nutritional repletion. We, like others, have shown improvement in a number of important functional indices with a course of IVN,[27,28] further emphasizing the importance of body protein stores in maintaining normal body function.

Acknowledgments

We wish to acknowledge the help of Dr. A. Beddoe, Dr. J. Sutcliffe, Dr. G. Knight, Dr. G. Witney, Miss Susan Gasgoine, and Mrs. Susan McWilliams in the measurement of patients under the care of Mr. J. Allan, Mr. A. Clarke, Mr. C. Maclaurin, Mr. W. Morris, and Mr. J. Shaw at Auckland Hospital.

Problems in General Surgery

Lloyd M. Nyhus, M.D., Editor.

This series of hardbound volumes features a symposium on a specific topic in general surgery in each issue. It serves as an outlet for the publication of original articles aimed at defining and suggesting solutions to difficult problems encountered in practice. Clinical problems are emphasized, with concentration on difficulties and complications. Leading authorities, chosen for their expert knowledge in their assigned topics, contribute articles on specific subjects, pooling the expertise of specialists for the benefit of generalists.

Published quarterly. Individual rate $59.00 per year (U.S.), $68.00 (elsewhere). Residents $39.00 (U.S. only).

Annals of Surgery

Official Publication of The American Surgical Association, The Southern Surgical Association, Philadelphia Academy of Surgery, and the New York Surgical Society

David C. Sabiston, Jr., M.D., Chairman of Editorial and Advisory Board.

Annals of Surgery—the world's oldest exclusively surgical journal—has provided the medical community with reports on significant contributions to the advancement of surgical science and practice for over 100 years. Its 20,000 subscribers find it a practical way to keep up to date with important developments in surgery.

Published monthly. Individual rate $53.00 per year (U.S.), $70.00 (elsewhere). Residents $35.00 (U.S.), $52.00 (Canada).

The American Surgeon

Official Publication of the Southeastern Surgical Congress, the Midwest Surgical Association, the Association of Clinical Anatomists, and the Society of American Gastrointestinal Endoscopic Surgeons (SAGES)

Arlie R. Mansberger, Jr., M.D., Editor-in-Chief.

An authoritative forum for the publication of original papers contributing to the advancement of surgery. Each issue contains information on the clinical application of new methods used in the management of patients; review articles with continuing education questions; condensed reviews of unusual case reports; "How I Do It" articles emphasizing the technical aspects of surgery.

Published monthly. Individual rate $49.00 per year (U.S.), $60.00 (elsewhere). Residents $32.00 (U.S. only).

Current Surgery

The Official Journal of the Association of Program Directors in Surgery

Lloyd M. Nyhus, M.D., Editor.

An internationally renowned editorial board prepares abstracts from every dependable source of surgical information throughout the world. Drawing on their own clinical experience and that of other recognized authorities, the members of the board provide commentary to further amplify and illuminate the material contained in each abstract. Also included are editorials, reports of new discoveries, residents' corner, and book reviews.

Published bimonthly. Individual rate $40.00 per year (U.S.), $46.00 (elsewhere). Residents $26.00 (U.S.), $32.00 (Canada).

Diseases of the Colon and Rectum

Official Journal of the American Society of Colon and Rectal Surgeons and the International Society of University Colon and Rectal Surgeons

Robert W. Beart, Jr., M.D., Editor-in-Chief.

This journal publishes reports on contemporary practice in the diagnosis and management of proctologic diseases and surgery. International in scope, it includes articles from physicians worldwide who share their important discoveries that offer new insights into basic research in metabolism, pathology, virology, radiology, and the clinical practice of medicine and surgery.

Published monthly. Individual rate $74.00 per year (U.S.), $89.00 (elsewhere). Residents $44.00 (U.S.), $59.00 (Canada).

Journal of Cardiovascular Surgery

Official Journal of the International Society for Cardiovascular Surgery

J. E. Connolly and S. S. Rose, Co-chief Editors.

The Journal is devoted to disease of the heart and the entire vascular system. It presents concise, informative coverage of the most significant work being done in diagnostic, experimental, and clinical surgery of the heart and blood vessels.

Published bimonthly. Individual rate $80.00 per year (North America only).

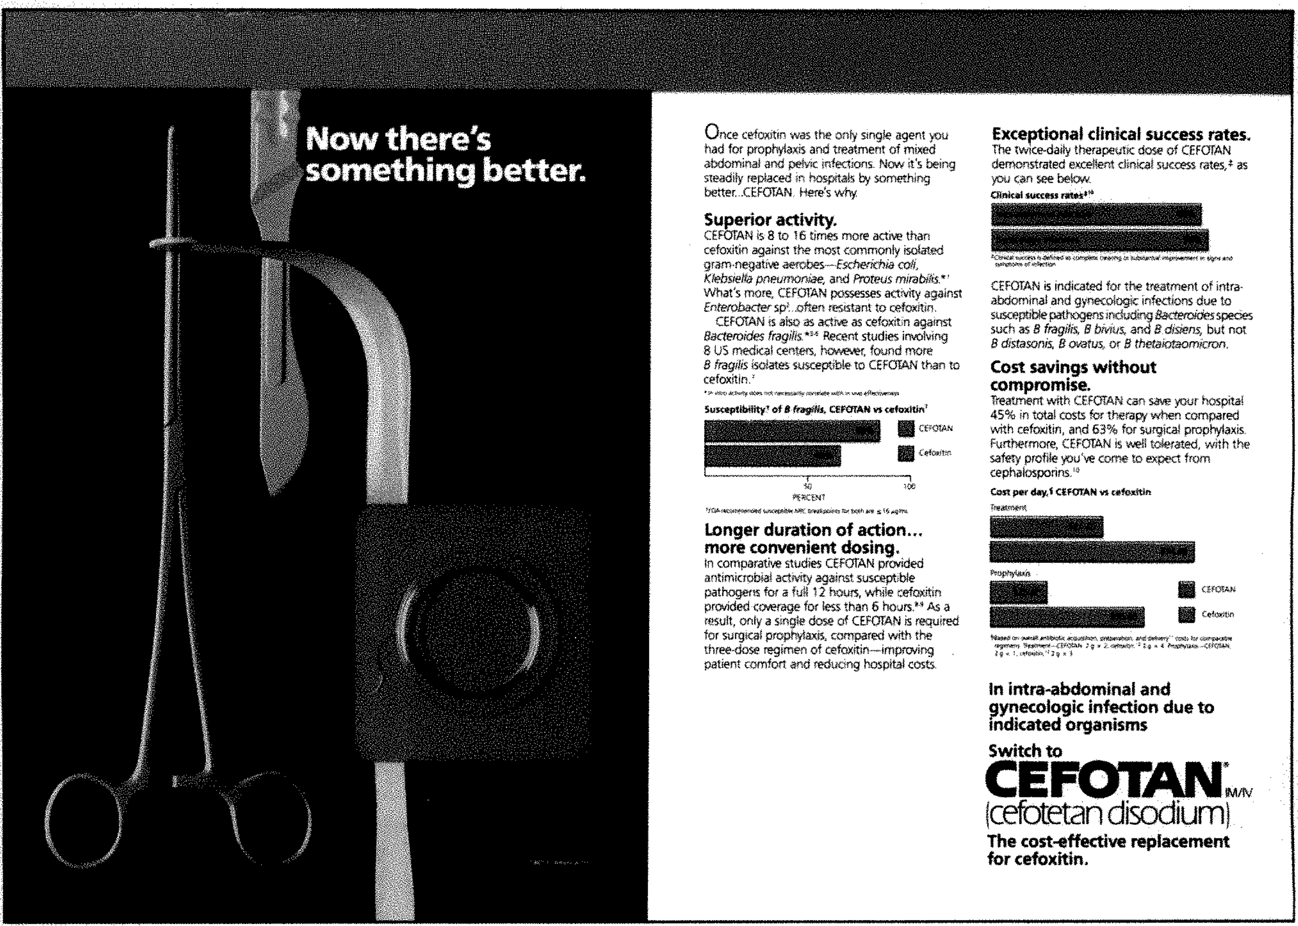
We said.[1]



Now there's something better.

Once cefoxitin was the only single agent you had for prophylaxis and treatment of mixed abdominal and pelvic infections. Now it's being steadily replaced in hospitals by something better...CEFOTAN. Here's why.

Superior activity.

CEFOTAN is 8 to 16 times more active than cefoxitin against the most commonly isolated gram-negative aerobes—*Escherichia coli, Klebsiella pneumoniae,* and *Proteus mirabilis.**[1] What's more, CEFOTAN possesses activity against *Enterobacter* sp[2]...often resistant to cefoxitin.

CEFOTAN is also as active as cefoxitin against *Bacteroides fragilis.**[3,4] Recent studies involving 8 US medical centers, however, found more *B fragilis* isolates susceptible to CEFOTAN than to cefoxitin.[7]

*In vitro activity does not necessarily correlate with in vivo effectiveness.

Susceptibility† of *B fragilis*, CEFOTAN vs cefoxitin[7]

†FDA-recommended susceptible MIC breakpoints for both are ≤ 16 µg/mL.

Longer duration of action... more convenient dosing.

In comparative studies CEFOTAN provided antimicrobial activity against susceptible pathogens for a full 12 hours, while cefoxitin provided coverage for less than 6 hours.[8,9] As a result, only a single dose of CEFOTAN is required for surgical prophylaxis, compared with the three-dose regimen of cefoxitin—improving patient comfort and reducing hospital costs.

Exceptional clinical success rates.

The twice-daily therapeutic dose of CEFOTAN demonstrated excellent clinical success rates,‡ as you can see below.

Clinical success rates‡[10]

‡Clinical success is defined as complete clearing or substantial improvement in signs and symptoms of infection.

CEFOTAN is indicated for the treatment of intra-abdominal and gynecologic infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis, B bivius,* and *B disiens,* but not *B distasonis, B ovatus,* or *B thetaiotaomicron.*

Cost savings without compromise.

Treatment with CEFOTAN can save your hospital 45% in total costs for therapy when compared with cefoxitin, and 63% for surgical prophylaxis. Furthermore, CEFOTAN is well tolerated, with the safety profile you've come to expect from cephalosporins.[10]

Cost per day,§ CEFOTAN vs cefoxitin

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin.

9. Hemsell DL, Wendel GD, Gall SA, et al: Multicenter comparison of cefotetan and cefoxitin in the treatment of obstetric and gynecologic infections. *Am J Obstet Gynecol*, submitted for publication.

*CEFOTAN is indicated for the treatment of intra-abdominal and gynecologic infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis*, *B bivius*, and *B disiens*, but not *B distasonis*, *B ovatus*, or *B thetaiotaomicron*.

We all agree.

CEFOTAN® IM/IV

(cefotetan disodium)

Does so much for so much less than cefoxitin

Please see next page for brief summary of prescribing information.

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV

(cefotetan disodium)

Does so much for so much less than cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

† Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients: the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

Submaximal Exercise During Intravenous Hyperalimentation of Depleted Subjects

YUMAN FONG, M.D., DAVID G. HESSE, M.D., KEVIN J. TRACEY, M.D., JAMES D. ALBERT, M.D., ADRIAN LEGASPI, M.D., MURRAY F. BRENNAN, M.D., F.A.C.S., and STEPHEN F. LOWRY, M.D., F.A.C.S.

The peripheral nitrogen wasting and loss of functional capacity caused by the malnutrition of disease and the immobilization of hospitalization may not be readily reversed by refeeding alone. In order to examine submaximal exercise as an adjunctive anabolic stimulus to intravenous refeeding (IVF) in depleted subjects, 14 volunteers were studied in the postabsorptive (PA) state, after 10 days of total starvation, and again after 10 days of nutritional repletion with I.V. feedings. The subjects were randomized to one group that received IVF alone and one group that performed 1 hour of submaximal (51% of $\dot{V}O_2$max) stationary bicycle exercise daily during IVF. The exercised group was not significantly different from the nonexercised group in urinary nitrogen balance, resting energy expenditure, extremity amino acid flux, or maximal oxygen consumption. Acute exercise did not induce significant derangements in electrolytes or counter-regulatory hormone concentrations. Ten days of submaximal exercise does not appear to be detrimental in this population recovering from moderate hospitalized malnutrition, but additional anabolic stimulae may be needed for improvements in protein accrual or functional capacity.

From the Laboratory of Surgical Metabolism and the General Clinical Research Center of the New York Hospital-Cornell Medical Center, and the Surgical Metabolism Laboratory of the Memorial Sloan-Kettering Cancer Center, New York, New York

HOSPITALIZED SURGICAL patients often suffer from progressive muscle wasting and loss of functional capacity secondary to both malnutrition and immobilization. Reversal of the poor nutritional intake alone by limited periods of adequate protein and caloric supplementation does not completely reverse these detrimental changes.[1] Since recovery from disease and early rehabilitation is thought to be associated with restoration of skeletal muscle protein stores, identification of effective stimulae for preservation and restoration of muscle mass and function would provide important adjuvants to nutritional therapy in hospitalized patients.

In isolated tissue studies and *in vivo* animal models, the stimulus that most consistently improves muscle protein balance is contractile activity.[2,3] Such activity reverses the ultrastructural changes seen with immobilization (loss of myofilaments and shrinkage of muscle fibers),[4] and may enhance protein synthesis even during unfavorable hormonal and nutritional conditions,[5] or in the presence of malignancy.[6]

Acute bouts of exercise can induce measurable changes in protein, carbohydrate, and lipid metabolism. These changes are characterized by an increase in body protein breakdown, a decrease in protein synthesis, and an increased utilization of protein for gluconeogenesis and lipids for oxidative fuel.[7-10] Chronic daily exercise, however, leads to adaptive processes that result in a net increase in total body as well as peripheral nitrogen stores.[11] Although the amount and frequency of exercise needed to bring about this adaptive process, or *training effect,* in normal humans is well studied, studies of the effects of chronic exercise in hospitalized humans are few.[12] Studies of exercise in the clinical setting of hospitalized, malnourished subjects during nutritional support are lacking.

The duration, intensity, and frequency of exercise that are needed for detectable improvements in either functional or metabolic parameters in this setting are unknown. Of perhaps equal importance is whether the acute or chronic effects of exercise in this setting would be detrimental to the subjects. These questions are important in planning physical rehabilitation of depleted patients.

Supported by NIH Grant Nos. GM34695, KO4GM-00505, and ACS-PDT261. Yuman Fong, M.D., is the recipient of a clinical fellowship from the American Cancer Society.

Submitted for publication: September 30, 1987.

In order to assess the impact of daily submaximal exercise on protein metabolism in this setting, we studied the effects of exercise on previously starved, healthy volunteers during IVF.

Methods

Subjects

Male volunteers were screened as outpatients by complete physical exam, blood count, and serum biochemistries. Fourteen subjects aged 21–31 years and within 10% of ideal body weight for age, sex, and height (Metropolitan Life Table, 1983) were admitted to the Adult Clinical Research Center (CRC) of the New York Hospital-Cornell Medical Center (NYH-CMC). The study was approved by the Institutional Review Board of the NYH-CMC, and informed written consent was obtained from each subject prior to enrollment in the study.

Study Protocol

The volunteers were admitted to the CRC for 24 consecutive days. Subjects were weighed daily at 6:00 AM after voiding. Daily 24-hour urine samples were collected. During the first 3 hospital days, each subject was fed orally with a defined formula diet (Sustacal, Mead-Johnson, Evansville, IN) in six equal portions daily. This diet was provided at 1.2 times the resting energy expenditure (REE) (33 ± 2 kcal/kg/d, 0.32 ± 0.01 gN/kg/d). Feedings were discontinued at 8:00 PM on hospital day 3 and at 7:00 AM on day 4, in the postabsorptive (PA) state; measurements of REE and extremity substrate flux were performed as outlined below.

From hospital days 4 to 14, a 10-day protein-calorie starvation period was achieved during which oral intake was limited to distilled water, no-calorie soft drink (provided *ad libitum*), and a tablet of sodium chloride (20 mEq/d). At 7:00 AM on hospital day 14 measurements of REE and substrate flux were repeated in the starvation (STV) state. A percutaneous catheter was then inserted into the antecubital vein and advanced into the superior vena cava (placement confirmed by chest roentgenography). All subjects received I.V. feeding from hospital days 14–24 with a commercially available amino acid source (aminosyn, 5%) and 100% of the nonprotein calories as D-glucose. The nutrients provided were 30 ± 2 nonprotein kcal/kg/d and 0.30 ± 0.02 gN/kg/d. Appropriate electrolytes, trace metals, and vitamins were added by previously described standards.[12]

From the time of admission until day 14 all subjects were allowed to ambulate within the ward but were restricted from any other physical activity. After beginning IVF the subjects were randomly selected to enter one of two physical activity groups. One group (−EX) (N = 7) continued to be restricted from any physical activity other than light ambulation within the hospital ward, while the other group (+EX) (N = 7) underwent 1 hour of daily upright bicycle exercise (Monarch Corp., Stockholm) at 51 ± 3% of $\dot{V}O_2$max. The exercise was performed between 5:00 PM and 6:00 PM each day during the I.V. feeding. On day 3 of the exercise regimen venous plasma electrolyte, glucose, catecholamine, glucagon, and cortisol levels were determined at 20-minute intervals during the 1-hour exercise period and at half-hour intervals for 1 hour after the exercise period.

On day 24 at 7:00 AM REE and substrate flux measurements were again made, this time under IVF conditions. On days 3, 13, and 23, maximal oxygen uptake ($\dot{V}O_2$max) determinations as described below were also made at least 12 hours before each metabolic study session.

Urinary Nitrogen Balance

Daily 24-hour urine collections were made. The samples were refrigerated and treated with sodium fluoride during collection and then frozen at −70 C immediately until analysis. After digesting the samples using a micro-Kjeldahl method, the total nitrogen was analyzed using the Technicon AutoAnalyzer-2 (Technicon, Tarrytown, NY). Urinary nitrogen balance was calculated as previously described.[13]

REE

Measurements of oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$) were performed in the supine position with a Beckman Metabolic Measurement Cart-1 (Sensormedics Corp., Anaheim, CA). This system contained an OM-11 oxygen analyzer and LB-2 carbon dioxide analyzer. The instrument was calibrated before and after each test using a minimum of two standard calibration gases (100% nitrogen, and 16%:4% oxygen:carbon dioxide).[14] REE was estimated using the de V. Weir formula [REE(cal/min) = $3.941 \times \dot{V}O_2 + 1.106 \times \dot{V}CO_2$].[15]

Extremity Substrate Flux

Percutaneous radial artery and retrograde venous catheters (basilic or femoral) were placed on days 4, 14, and 24. Arterial and venous samples for substrate analysis were drawn simultaneously from the catheters. Blood flow to the extremity was determined before and after the blood sampling using electrocapacitance plethysmography.[16] Four of the nonexercised subjects had leg flux determinations while three had nondominant arm flux determinations. All exercised subjects had determinations of leg substrate flux only. Plasma amino acid flux was calculated as (arterial concentration − venous concentration) × blood flow × (1 − hematocrit). A posi-

† $p < 0.05$ *versus* STV.

tive value represents a relative uptake across the extremity whereas a negative value indicates a net efflux of amino acids out from the extremity.

Substrate Concentrations

Plasma amino acids, including glutamine,[17] were determined by column chromatography on a Beckman 119CL amino acid analyzer (Beckman Instruments, Fullerton, CA) using a three-buffer lithium system with ethyl-cysteine as an internal standard.[18] Cortisol was measured by radioimmunoassay.[19] Plasma for glucagon was collected with EDTA and aprotinin prior to analysis by radioimmunoassay.[20] Epinephrine, norepinephrine, and dopamine levels were determined by radioenzymatic assays.[21]

Blood count, electrolytes, glucose, and liver function tests were analysed using standard automated techniques available in the NYH-CMC Clinical Biochemistry Laboratories.

$\dot{V}O_2max$

$\dot{V}O_2$max was determined by stepwise bicycle ergometry (25–125 watts) using the linear relationship between $\dot{V}O_2$ and heart rate.[22] Subjects underwent continuous heart rate monitoring by ECG and $\dot{V}O_2$ determinations every 30 seconds for the study. Heart rate and $\dot{V}O_2$ were determined under basal conditions and during 4-minute intervals of incremental submaximal exercise. Mean heart rates (y axis) were plotted against $\dot{V}O_2$ (x axis) and linear regression analysis performed for each study. Using 220 − age as an estimated maximal heart rate,[23] $\dot{V}O_2$max was calculated as:

$$[(220 - \text{age}) - y \text{ intercept}]/\text{m},$$

where m is the slope of the linear regression line of the heart rate against $\dot{V}O_2$ under basal and submaximal exercise conditions.

Statistical Analysis

All data are expressed as mean ± SEM. Standard paired and unpaired Student's t-tests were used for single comparisons. ANOVA and Newman-Keuls tests, where appropriate, were used to identify statistical significance for multiple comparisons.

Results

Patient Groups

The average age of the volunteers in the exercised group was comparable to that in the nonexercised group (Table 1). The volunteers randomized to the nonexercised regimen had a higher average initial weight than those randomized to the exercise program (80 ± 3 kg *vs.* 73 ± 3 kg). However, both groups lost a similar per cent of body weight with 10 days of starvation (−8% *vs.* PA and −7% *vs.* PA). Both groups also exhibited similar weight recovery during IVF, reaching within 3% of initial weight in nonexercised subjects and 2% of initial weight in exercised subjects (Table 1). Thus, both groups demonstrated similar levels of depletion and subsequent repletion with the experimental regimen.

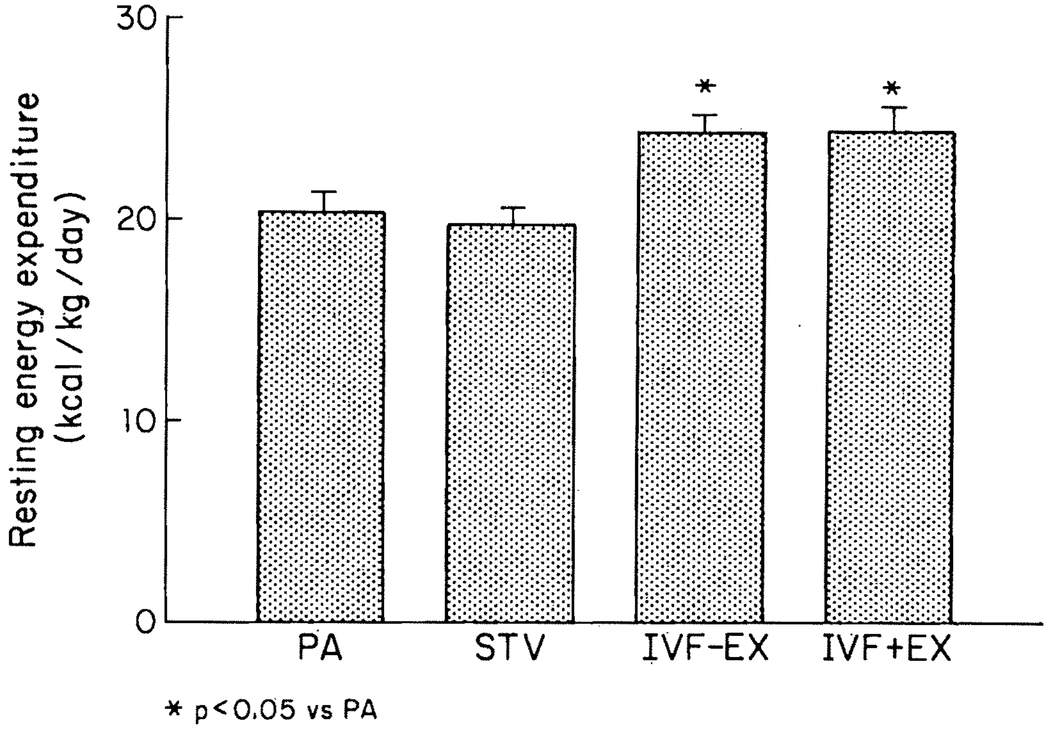

FIG. 1. REE was determined in the PA (N = 14), STV (N = 14), I.V. feeding without daily exercise (IVF − EX) (N = 7), and I.V. feeding with daily exercise (IVF + EX) (N = 7) conditions.

Serum Chemistries

Serum albumin levels were not significantly changed throughout the course of the experiment and were comparable in the exercised and nonexercised groups (Table 1). In agreement with previous reports, glucose levels decreased after 10 days of starvation and then rose during refeeding with the glucose-based parenteral feeding.[24] The values for both groups remained within the normal range for liver function tests throughout the study and were not statistically different between the groups.

REE

The REE was similar in the PA and the STV states (20.4 ± 0.9 and 19.8 ± 0.8 kcal/kg/d) (Fig. 1). REE rose significantly with IVF to 24.4 ± 0.9 in the nonexercised group and 24.5 ± 1.0 in the exercised group (both $p < 0.05$ *vs.* PA).

Urinary Nitrogen Balance

Negative nitrogen balance in the PA state (−0.12 ± 0.01 gN/kg/d) decreased significantly after starvation (−0.095 ± 0.009 gN/kg/d), indicating a degree of nitrogen sparing with starvation (Fig. 2). This is similar to levels previously reported in starved man.[13,25] With IVF both the exercised and nonexercised groups reached positive nitrogen balance by the second day of I.V. feeding. There were no significant differences of nitrogen balance between the two groups throughout the course of the study [0.12 ± 0.01 in the nonexercised (−EX) group and 0.11 ± 0.01 gN/kg/d in the exercised (+EX) group].

Extremity Amino Acid Flux

The total amino acid flux (TAA) across the extremity in the PA state was −950 ± 150 nmol/min/100 mL tissue (Table 2), similar to previous reports.[1] With starvation, efflux decreased to −700 ± 160 nmol/min/100 mL tissue, suggesting nitrogen sparing within the extremity. With refeeding, TAA flux in the group randomized to the exercise regimen and the group randomized to the nonexercise regimen, both rose significantly, to −39 ± 48 and +30 ± 160, respectively, but not statistically different between the two groups.

Only the flux of the amino acids serine and methionine showed significant differences between the exercised and nonexercised groups during IVF. All other amino acids, either alone or grouped as essential amino acids (EAA), branched chain amino acids (BCAA), or glutamine and alanine (G + A) were without significant differences in flux between the two groups during IVF (Fig. 3).

$\dot{V}O_2$

The group randomized to nonexercise had an initially higher $\dot{V}O_2$max (35 ± 1 mL/kg/min) than the group chosen to exercise (30 ± 3 mL/kg/min) (Fig. 4). Both groups demonstrated a similar percentage decline in $\dot{V}O_2$max with starvation (−10% *vs.* PA and −11% *vs.* PA). With IVF both groups showed a similar further

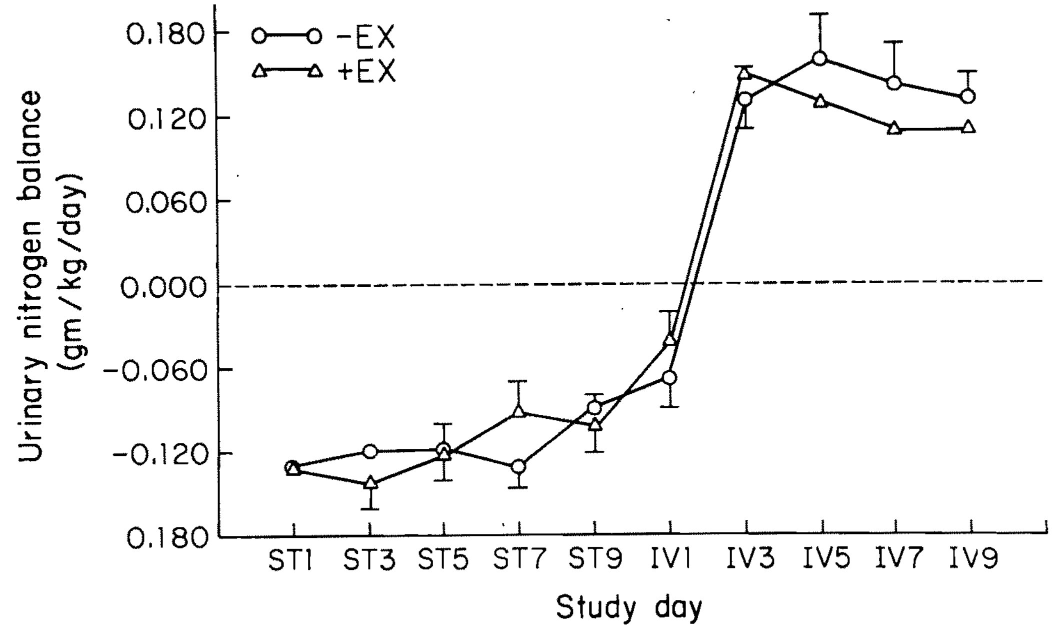

FIG. 2. Urinary nitrogen balance in exercised (+EX) and nonexercised (−EX) subjects. The data are plotted during ST and during IVF. Results are given as means ± SEM. There were no statistically significant differences between the two groups.

percentage decline in $\dot{V}O_2$max to −20% and −22% compared with the PA values.

Acute Electrolyte and Hormonal Changes with Exercise

There were no statistically significant changes in electrolyte or glucose levels during or immediately after an exercise session during IVF (Table 3). Venous epinephrine and dopamine levels rose significantly during the exercise session but remained in a low range and returned to pre-exercise levels within 1 hour of exercise. Serum concentrations of cortisol, glucagon, and norepinephrine also demonstrated slight increases during exercise, but these increased levels were not statistically different from baseline.

Discussion

It is estimated that 50% of all hospitalized patients exhibit overt clinical signs of malnutrition.[26] It is frequent in the surgical population, whether because of underlying disease or surgical procedures, that patients undergo periods of fasting and hospitalized immobilization. Significant total body and peripheral protein wast-

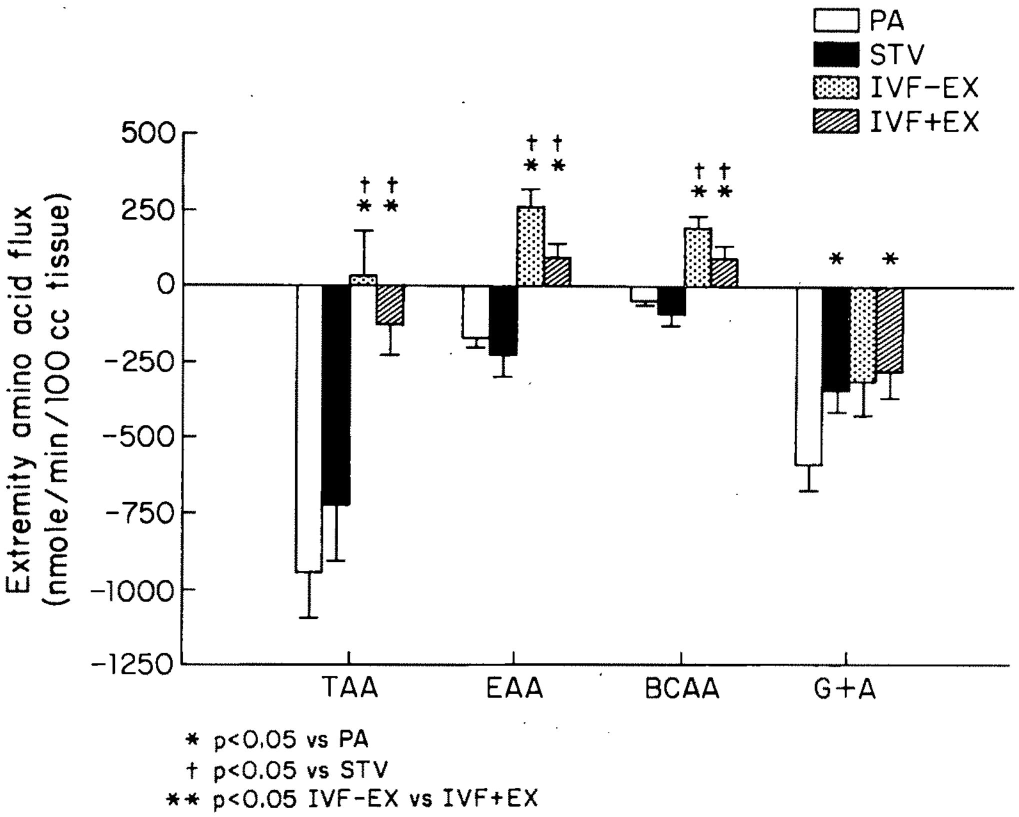

FIG. 3. Extremity amino acid flux of TAAs, EAAs, BCAAs, and the sum of glutamine and alanine (G + A). Measurements were performed in the PA, STV, I.V. feeding without daily exercise (IVF − EX), and I.V. feeding with exercise (IVF + EX) conditions. A positive value indicates extremity uptake of amino acids and a negative value indicates an efflux of amino acids from the extremity.

ing can be seen after as little as 4 days of in-hospital bed rest.[27]

Previous studies have examined the efficacy of chronic submaximal exercise used in conjunction with I.V. alimentation in reversing the negative effects of hospitalized immobilization.[12,28] In those studies, daily submaximal exercise in hospitalized but well nourished volunteers was observed to be associated with improve-

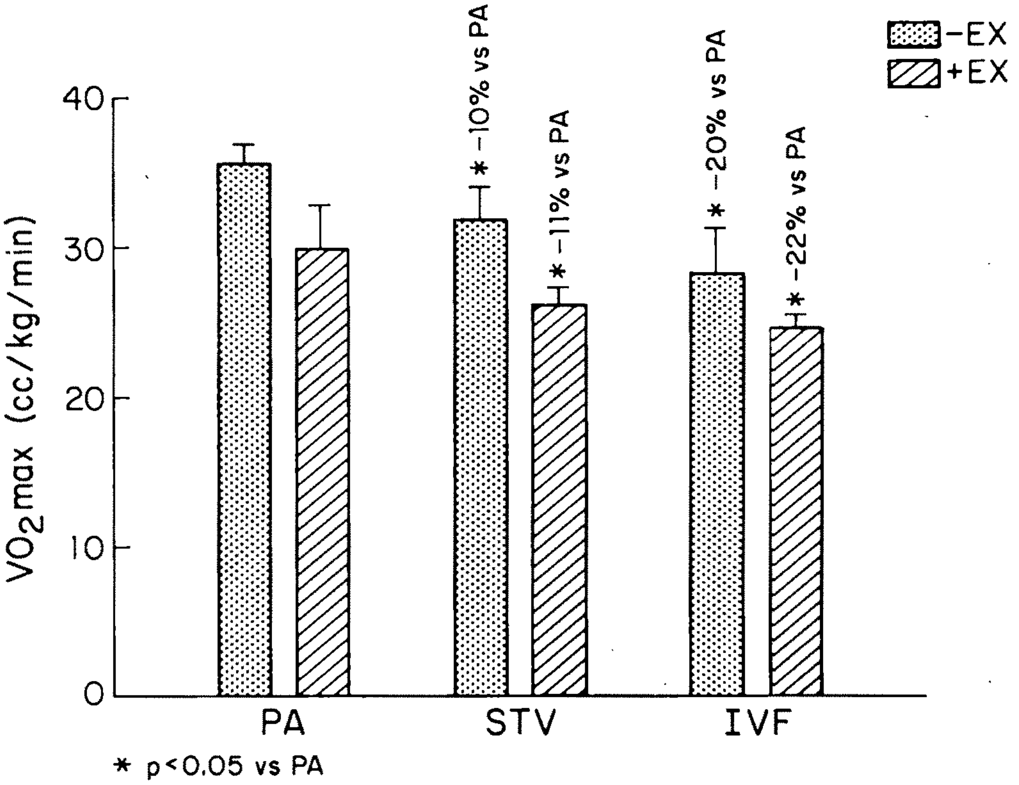

FIG. 4. Maximal oxygen uptake measured during PA, STV, and IVF conditions. The data are presented for nonexercised (−EX) and exercised (+EX) subjects. The per cent change *versus* the PA condition is indicated above the bars.

ments in total body and extremity nitrogen balance. The effects of such an exercise regimen, however, in the clinically relevant setting of immobilization compounded by malnutrition remained uncharacterized.

Since the amount of training improvement is known to be inversely related to the prior fitness level,[29] employing an untrained population allows the best opportunity for detecting any improvement brought on by the exercise regimen. Therefore, we chose to examine chronic submaximal exercise as an adjunct to IVF in a disease-free volunteer population subjected to hospitalized immobilization and malnutrition. The selection of healthy volunteers avoids the confounding variability inherent to comparisons of patients with different illnesses and differing degrees of stress-induced hypermetabolism.

The level of exercise in this study was chosen for its potential clinical applicability. It has been demonstrated[30] that this level of exercise has been able to bring about a training effect in well-nourished volunteers. It is also the most vigorous regimen that we thought can be reasonably expected of an ill, hospitalized, and possibly postsurgical population. However, 10 days of daily submaximal exercise at this intensity did not improve the total body or peripheral nitrogen accrual in the current study population.

We did verify that adequate nutritional supplementation via the I.V. route is able to abate the total body and peripheral nitrogen losses seen in otherwise unstressed but malnourished hospitalized subjects. While this supplementation is sufficient in promoting total body nitrogen accrual, we did not observe any net muscle-specific amino acid uptake.

Hospitalized patients demonstrate a progressive loss of functional capacity as measured by $\dot{V}O_2$max,[11] and this loss in functional capacity can be detected within 4 days.[27] Since early rehabilitation and return to premorbid and useful activity is thought to be facilitated by a preservation of functional capacity, methods of preserving or improving functional capacity have long been investigated. It has been demonstrated that nutritional supplementation alone, either in the form of hypocaloric glucose or amino acid supplementation,[31,32] was not effective in preserving functional capacity in postoperative patients. Intravenous hyperalimentation alone in hospitalized volunteers was also not effective in preserving functional capacity.[12]

The current study demonstrates that the immobilization of hospitalization and malnutrition are sufficient stimulae in bringing about a decline in $\dot{V}O_2$max. The degree of change is similar to a previous report of the change in $\dot{V}O_2$max in an otherwise healthy volunteer population subjected to 20 days of bed rest alone without depletion.[33] In contrast to nondepleted subjects, however, the current study shows that 10 days of chronic submaximal exercise was not adequate in previously depleted subjects of alleviating the further detraining effects of hospitalization, even in the setting of adequate I.V. repletion. The REE, which is related to physical conditioning,[34] also demonstrated no detectable difference between the exercised and nonexercised groups at the end of the IVF period.

It is important to note that the exercise regimen explored in the current study did not produce significant acute or chronic detrimental effects in this population during refeeding. Previous investigators observed that unfed normal volunteers may develop hypoglycemia during acute exercise.[35] Counter-regulatory hormone rises have been observed with exercise and seem to be inversely related to the subject's level of physical conditioning.[36] Therefore, it is a legitimate concern that physical activity in a depleted, detrained population such as this may cause intolerable, detrimental hormonal or substrate changes. The present data, however, show that potassium and glucose levels remained unchanged during acute exercise and counter-regulatory hormone changes were acceptably small during the bouts of exercise. This suggests that the acute effects of exercise at the current level were well tolerated in this setting of recovery from the fasting-induced catabolic state. The cumulative effects of the 10 days of submaximal exercise also did not seem detrimental to the subjects in any of the measured parameters. Thus, mobilization and physical rehabilitation might safely be initiated early in the recovery from hospitalization and moderate malnutrition.

Since training improvement seems to be directly related to training intensity and duration,[29] perhaps a higher level of exercise, longer daily bouts of exercise, or more days of exercise will produce detectable benefit in this population. Higher levels of exercise or longer bouts, however, are probably not clinically applicable options.

In summary, IVF in the setting of hospitalized immobilization was able to restore total body protein but was less successful in restoration of skeletal muscle mass. The addition of 10 days of daily submaximal exercise did not significantly impact upon the peripheral accrual of nitrogen in this previously depleted population. Therefore, additional anabolic stimulae might be used in an adjuvant setting both to affect earlier restoration of lean body mass as well as to supplement the functional response to submaximal exercise.

Financial Risk, Hospital Cost, Complications, and Comorbidities in Surgical Noncomplication- and Noncomorbidity-stratified Diagnostic Related Groups

ERIC MUÑOZ, M.D., M.B.A., HARRIS STERMAN, M.D., JON COHEN, M.D., JONATHAN GOLDSTEIN, M.P.A.,
IRVING B. MARGOLIS, M.D., and LESLIE WISE, M.D.

The purpose of this study was to analyze resource consumption in the 147 non-complicating condition–stratified surgical diagnostic related groups (DRGs). Analysis of 2647 surgical patients in these non-CC–stratified surgical DRGs demonstrated that patients with more CCs per DRG generated higher total hospital costs, a longer hospital length of stay, a greater percentage of procedures per patient, financial risk under DRG payment, more outliers, and a higher mortality rates than patients in these same DRGs with fewer CCs. These findings suggest that the current DRG classification system may be inequitable to certain groups of patients or types of hospitals vis-à-vis the non-CC–stratified surgical DRGs. Financial disincentives to treat these patients may affect both their access and quality of care in the future.

From the Department of Surgery, Queens Hospital Center, and the Long Island Jewish Medical Center, New Hyde Park, New York; State University of New York, Stonybrook, New York

MEDICARE'S NEW Diagnostic Related Group (DRG) hospital payment system has introduced financial risk for hospitals treating certain groups of patients.[1,2] Some hospitals, such as teaching or public hospitals, which treat a more severely ill patient or more emergency admissions, may be underreimbursed by DRGs for the greater cost of these patients.[3,4] DRGs were constructed to consider some factors that contribute to higher hospital expenses per patient. Surgical DRGs are grouped in an attempt to provide appropriate reimbursement to hospitals based on the type of operative procedure. Some surgical DRGs are stratified for a given operation for patients who have complications or comorbidities. These patients receive higher DRG reimbursement. At the present time 147 of the 250 surgical DRGs (58.8%) are *not* stratified by the presence or absence of a complication (*i.e.*, a condition present after admission to the hospital) or a comorbidity (*i.e.*, a condition present on admission to the hospital).[5] The purpose of this project was to analyze resource consumption in the noncomplication- and noncomorbidity-stratified surgical DRGs, and to test the hypothesis that financial risk would be generated by patients who had a greater number of CCs in these DRGs.

Methods

All Medicare surgical patients (N = 2647) admitted to the Long Island Jewish Medical Center (an 805-bed teaching hospital in suburban New York City) in any of the 147 non-CC–stratified surgical DRGs from January 1, 1985 to December 31, 1986 were studied. Our hospital is categorized as an urban teaching hospital by the DRG reimbursement scheme; standard New York State DRG methodology was used for this analysis. All general surgery and surgical subspecialty patients (*e.g.*, ENT, orthopedic, neurosurgery, *etc.*) in these non-CC–stratified DRGs were studied. The assessment of CCs was calculated by the number of ICD-9-CM diagnostic codes (as a proxy for CCs) per patient. Patients with only one ICD-9-CM code were grouped as having no CCs; patients with two ICD-9-CM codes, one CC; patients with three ICD-9-CM codes, two CCs; *etc.* Patients were grouped into four categories: all patients with no CCs, all patients with 1 or 2 CCs, all patients with 3 or 4 CCs, and all patients with over 4 CCs.

Hospital costs for each CC group (exclusive of MD fees) were computed for each patient by hospital service area to include the following: room and board, laboratory (urinalysis, hematology, coagulation, biochemistry, and microbiology), radiology, blood and blood products, operating room/recovery room, central supply/pharmacy, and other (ECG, pathology, respiratory therapy, *etc.*). A number of characteristics were analyzed for

each patient including mean total hospital cost per patient, mean hospital cost per patient for each hospital service, mean DRG reimbursement per patient, mean profit/loss per patient, mean hospital length of stay (LOS) per patient, the mean number of diagnostic codes (ICD-9-CM) per patient, the mean number of procedure codes (ICD-9-CM) per patient, the per cent outliers, and mortality rates. In addition, four clinical characteristics were analyzed for each CC category such as surgical intensive care unit (SICU) admission, the requirement for plasma products (*i.e.*, blood products), need for blood transfusion (*i.e.*, red cells), and the need for emergency (ER) admission. The ANOVA was used to test for statistical significance between groups of patients. Linear regression analysis was performed to test the relationship between total hospital cost *versus* the number of CCs per patient. In order to account for per patient differences in DRG weight index, the linear regression equation was total hospital cost per patient/DRG weight index per patient *versus* number of CCs per patient.

Hospital Costing Methodology

Hospital cost per patient was obtained by utilizing per patient charge specific data and converting these charges to hospital costs. Cost to charge ratios utilized by our hospital accounting division were used to convert charges to costs. The ratios used for each hospital service category are listed in Table 1. To obtain the hospital cost for diagnostic radiology of \$100, the following calculation was performed (\$100 × 0.94 = \$94); medical supplies (\$100 × 1.00 = \$100); blood (\$100 × 1.15 = \$115); and so on.

Results

The mean DRG weight index per patient for all 2647 patients was 1.9198 (Table 2). Mean DRG weight index per patient rose as the number of CCs per patient increased; highest was for patients with over 4 CCs per patient, 2.7554. This relative increase in DRG weight index with increasing CCs should be kept in mind as resource consumption per patient is analyzed. Patients with over 4 CCs per patient had a 193% greater mean DRG weight index than patients with no CCs per patient. Mean hospital LOS per patient for all patients was 12.5 days; highest hospital LOS was for patients with over 4 CCs per patient, 29.5 days (a 447% greater hospital LOS than for patients with no CCs). The mean profit per patient under DRG reimbursement was \$419; patients with over 4 CCs, however, generated a \$9,556 loss per patient (\$3,812,844 aggregate loss for these patients). The mean number of diagnoses per patient for all patients was 3.17, and the mean number of procedures per patient 2.73. The number of procedures increased as CCs accumulated.

The mean total hospital cost per patient for all patients was \$11,271. Mean hospital cost increased as CCs per patient rose; highest hospital cost per patient was for patients with over 4 CCs, \$27,157 (a 436% greater cost than for patients with no CCs). In order to equilibrate the effect of DRG weight index for cost per patient, a ratio was computed of mean hospital cost per patient divided by the DRG weight index per patient for each CC category. This ratio was as follows: no CCs, 4,360; 1 or 2 CCs, 4,692; 2 or 3 CCs, 5348; and over 4 CCs, 9,855. Thus *relative* hospital cost per patient rose (keep-

ing DRG weight index constant) as the number of CCs per patient increased (the ratio was 226% greater for patients with over 4 CCs *vs.* patients with no CCs). Mean total hospital cost by hospital service demonstrated considerable variation among CC groups, but almost always increased as CCs per patient increased (Table 3). The largest component of total hospital cost was for room and board, followed by operating room/recovery room, other, laboratory, radiology, central supply/pharmacy, and blood.

The per cent of outliers rose as CCs per patient increased; patients with over four CCs had a 23% outlier rate (Fig. 1). The percent mortality rose as CCs per patient accumulated; patients with over 4 CCs had almost a 20% mortality rate (Fig. 2). Clinical resource utilization increased as CCs per patient rose for SICU utilization (Fig. 3), plasma products utilization (Fig. 4), blood utilization (Fig. 5), and emergency admission (Fig. 6). Linear regression analysis demonstrated an R^2 value of 0.10 ($p < 0.0001$) for total hospital cost (corrected for DRG weight index per patient) *versus* the number of CCs per patient.

Discussion

The purpose of this study was to analyze hospital resource consumption for Medicare surgical patients in the 147 non-CC–stratified surgical DRGs. Patients with a greater number of CCs per DRG had greater resource consumption than patients in these same DRGs with fewer CCs. Only about 50% of this greater resource consumption was explained by a higher DRG weight index. Thus, more CCs per patient per DRG generated greater total hospital cost, a longer hospital LOS, financial losses under DRG reimbursement, more procedures per patient, a greater proportion of outliers, and a higher mortality rate compared to patients in these same DRGs with fewer CCs per patient. These findings raise the question of the equity of DRG reimbursement vis-à-vis surgical patients in these non-CC–stratified surgical DRGs. This study suggests that patients in these DRGs with a greater number of CCs may be an *unattractive* population for hospitals.

At this time the Congress of the United States, the Health Care Financing Administration (HCFA) and the Prospective Payment Assessment Commission (ProPAC) are examining potential solutions to improve the equity of DRG hospital payment along the lines suggested in this study. Two ProPAC recommendations, for example, would further stratify some DRGs by CCs. Recommendation no. 21 contained in the April, 1987 report to the Secretary of Health and Human Services states, "DRGs should be defined on the basis of the

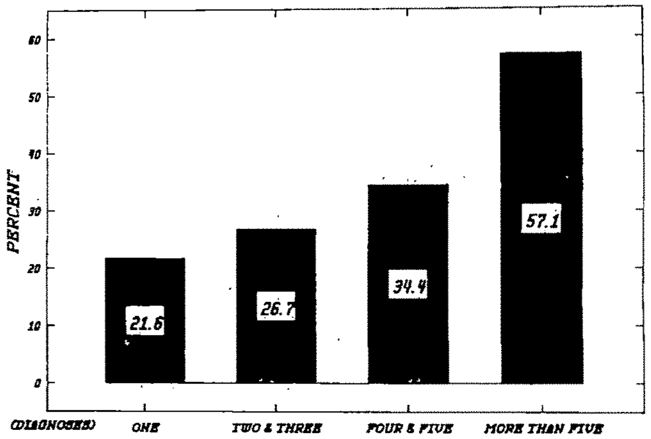

FIG. 5. More than 50% of patients with over 5 diagnoses required blood.

presence of a CC, regardless of age. . . . *The Secretary should determine whether other DRGs should also be split on CC.*"[6] Our study demonstrates that *other DRGs* (*i.e.*, many of the non-CC–stratified surgical DRGs) should be split by CC. In addition, ProPAC recommendation no. 22 in this same report states, "The Secretary should evaluate several possible approaches, *including DRG-specific CCs on the basis of resource intensity,* and the specification of levels of complexity among the CCs."[7] This ProPAC recommendation is also supported by our findings for the non-CC–stratified surgical DRGs. However, critics of these proposals contend that providing further incentives to modify DRGs by CCs will result in another round of *DRG creep,* namely, hospital incentives to find more CCs per medical record. Thus, it is unclear whether an additional modification of some surgical DRGs will be implemented along the lines of CC splits, or what form this modification might take.

Another possibility involves stratifying surgical DRGs for severity of illness (*i.e.*, the degree of each patient's illness).[8] There are a number of methods being studied by the federal government as potential DRG severity modifiers. Several of these require substantial additional data collection by hospitals that would require extra administrative costs. In addition, critics maintain that none of the systems are sufficiently mature or widely enough tested to be implemented for the 11 million annual Medicare acute hospitalizations at the 6000 U.S. hospitals. Thus, it appears likely that no DRG severity modifier will be implemented in the near future.

It appears that the practicing surgeon is being placed between diminishing hospital resources to treat patients and an increasing scrutiny of the quality of that surgical care.[9] This study demonstrates that resource dilemmas may become a significant problem for treating certain types of patients or for certain groups of hospitals regarding the non-CC–stratified surgical DRGs analyzed here. Although surgeons must be sensitive to the increasing problem of scarce resources in the care of surgical patients, we must also emphasize equitable hospital

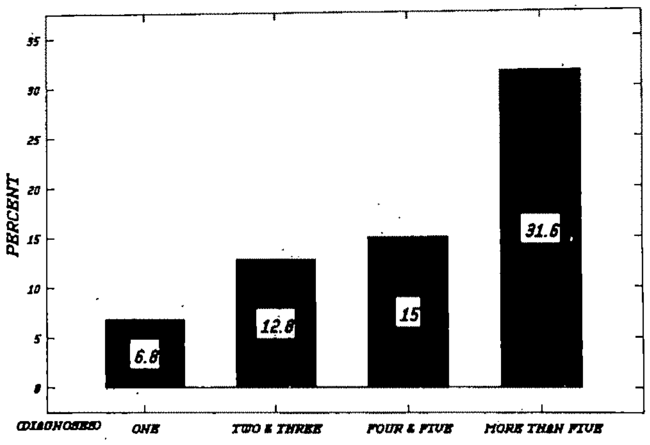

FIG. 4. Plasma product utilization was highest for patients with over 5 diagnoses.

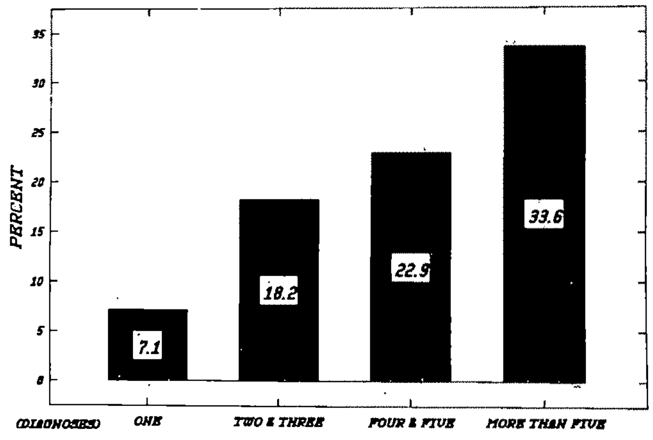

FIG. 6. Emergency admission rose with the number of diagnoses; one third of patients with over 5 diagnoses were emergencies.

payment for the treatment of surgical diseases. Surgeons must continue to analyze the equity and efficiency questions facing the field of surgery and advocate equitable high quality surgical care.

Conclusions

This study of 2647 surgical patients treated at an academic medical center analyzed the equity of the 147 non-CC–stratified surgical DRGs. Our data demonstrated that patients in these DRGs with more CCs per DRG had greater resource consumption, higher financial risk, and a poorer outcome than patients in these same DRGs with fewer CCs. This study thus suggests that the current DRG system is inequitable vis-à-vis groups of patients and types of hospitals treating patients in these non-CC–stratified surgical DRGs.

Acknowledgments

Reoperations for Persistent and Recurrent Secondary Hyperparathyroidism

MATTHIAS ROTHMUND, M.D., and PETER K. WAGNER, M.D.

Forty-nine reoperations for persistent or recurrent secondary hyperparathyroidism (HPT) in 30 patients are reported. The patients are part of a total of 184 patients operated on for secondary HPT; 28 reoperations in 18 patients were performed in the neck or in the upper mediastinum for remaining glands. Eleven reoperations at the forearm autograft revealed hyperplasia of the grafted tissue as the reason for recurrent disease in seven patients; they were treated by excision of all grossly enlarged particles. Ten patients received autologous cryopreserved tissue because of permanent postoperative hypoparathyroidism. The rate of graft-dependent recurrent HPT was 7%, and inadequate graft function was found in 6% of the patients.

From the Department of Surgery, Philipps University, Baldingerstraße, West Germany

Experience in surgical treatment of secondary hyperparathyroidism (HPT) has been accumulated since 1960.[1] Today the treatment of choice is total parathyroidectomy and immediate autotransplantation of fresh parathyroid tissue into the forearm muscle; however, some authors prefer subtotal parathyroidectomy. There are a considerable number of reports on both procedures for secondary HPT.[2] Results on reoperations for this disease have only once been published.[3]

The reasons for reoperations based on the failure to find all hyperfunctioning tissue in the neck are comparable in primary and secondary HPT. This is not true for the continued postoperative stimulation of growth and function of parathyroid tissue in secondary HPT—in the neck or at the graft site—due to chronic renal failure. This stimulus can only be stopped by renal transplantation. Inadequate function of the grafted tissue is a further problem that deserves to be managed.

The indications for reoperations in secondary HPT are the same as for the first operation: normocalcemia combined with markedly elevated alkaline phosphatase and radiologic signs of renal osteopathy (stage II) or the hypercalcemic variant of secondary hyperparathyroidism (stage III of the classification proposed in Table 1).[4] Persistence of secondary HPT can be defined in the same way as in primary HPT, namely, as the persistence or recurrence of the typical symptoms, laboratory parameters, and radiologic signs within 6 months.[5] A later occurrence of symptoms and signs of secondary HPT should be classified as recurrence.

Patients and Methods

Between 1975 and February 1987, 184 patients were operated on for secondary HPT. Thirty of these had 49 reoperations for recurrent or persistent disease or for permanent postoperative hypoparathyroidism (Table 2). There were 17 males and 13 females with ages ranging from 17 to 55 years (median: 32 years). All were receiving chronic maintenance hemodialysis.

Reoperations in the Neck

In 18 patients a total of 28 reoperations in the neck were performed, one reoperation in 12 patients each, two in 3, three in 2, and four in 1 patient. Ten of these 28 reoperations were unsuccessful, four in our own institution. During the 18 initial operations and the 10 unsuccessful reoperations 45.5 glands were removed (Table 3).

The following 18 and up until the current final reoperations in the neck in these 18 patients form part of this report. The time interval between the first operation and the last procedure was between 4 weeks and 19 years (median: 28 months). The indication for these reoperations was stage II disease in five patients, 4 months to 9

Indication for surgery	None	Relative, depending upon severity of fibro-osteoclasia	Absolute

years after the first procedure and in the other 13 patients stage III of secondary HPT according to the classification given in Table 1. In five of these 18 patients a recurrence of the disease was noted 29 months to 9 years after the first procedure. In the other 13 patients persistent secondary HPT was present. Some of the patients were investigated by sonography, CT scan, MRI, and thallium-technetium-subtraction scan for preoperative localization. The procedures were helpful only in the minority of the patients. We therefore restrict the use of these procedures even before reoperations, relying more on the surgical anatomy of the parathyroid glands.

In the 18 final reoperations another 31.5 parathyroid glands were removed (Table 4). Added to the 45.5 glands previously removed, this gives a total of 77 glands in 18 patients, which means an average of 4.3 glands were removed per patient. In ten of the 18 patients the glands were found in the mediastinum, in nine of these in the thymus. Five of the glands removed must be considered as supernumerary fifth glands. They were all excised by cervical thymectomy. The other glands were found in the neck.

In two of these patients the capsule of a parathyroid gland had been inadvertently opened and parathyroid cells were spilled in the operative field. Though macroscopically this material was removed completely, dispersed cells obviously grew in the neck, causing recurrent disease. One of these patients needed three reoperations finally removing all fat and connective tissue at this side of the neck until he was completely cured. Histology showed multiple distributed islets of hyperplastic parathyroid tissue in the specimen.

In 16 of the 18 patients calcium levels have remained normal after their last operation. Normal calcium levels have been established by a number of procedures. In six patients fresh parathyroid tissue was autografted in a forearm muscle since during all procedures a minimum of four parathyroids was excised, proved by histology. Four patients had no parathyroid function after the final operation and received a deferred autograft of cryopreserved tissue. Three other patients have normal serum calcium levels without autografted tissue after removal of two, three, and five glands, respectively. One patient was normocalcemic after removal of the fifth gland, with a normal functioning autograft, which was performed earlier. The same is true for the two patients where parathyroid cells had been inadvertently distributed in the operative field. One patient displays continuous hypercalcemia despite the resection of four glands in the neck and the removal of the autografted tissue in the forearm. One patient is hypocalcemic after removal of four glands. He will be autografted in the near future.

As complications of all reoperative procedures in the neck, one permanent and one transient recurrent nerve palsy was noted. There was no other postoperative morbidity nor mortality.

Graft Excision at the Forearm

In nine patients 11 procedures at the forearm graft were performed. All patients were preoperatively classified as having recurrent disease 32 to 80 months after autotransplantation of fresh tissue (median: 42 months). Hyperfunction after replantation of cryopreserved tissue

was not noted up to now. The indication for resection of the graft was in seven patients stage III, in two stage II of secondary HPT (Table 1) with recurrence of symptoms and signs of renal osteopathy. In eight patients hyperplastic tissue in the forearm was palpable as solitary or multiple nodules, which it could be visualized by sonography (Fig. 1). Additionally, in four patients a thallium scan was performed, which also displayed the autografted hyperplastic tissue (Fig. 2). In one patient there was no tissue palpable nor demonstrable by the imaging procedures.

The diagnosis of recurrent graft dependent HPT by determination of parathyroid hormone in the blood taken from the antecubital vein of the grafted *versus* the contralateral arm was not successful despite the fact that a highly sensitive midregional assay was used and blood was taken 1, 3, and 5 minutes after applying a tourniquet. Only two of the nine patients had a gradient of the grafted *versus* the contralateral side of 2 to 1 and 5 to 1, respectively. It should be noted that parathyroid hormone levels even at the contralateral side were 25 to 30 times normal. In the other seven patients without a demonstrable gradient, background levels of parathyroid hormones were between 3 and 80 times normal (mean: 38 times normal). In two of the nine patients postoperatively the hypercalcemia was not considered as graft-dependent. One of them remained hypercalcemic after excision of parathyroid tissue at the graft site. Later evaluation showed hyperfunctioning tissue in the neck. In the second patient the graft site was explored without finding any parathyroid tissue. He remained hypercalcemic until spilled hyperplastic parathyroid tissue in the neck was resected. These two patients belong to the aforementioned group of 18 patients reexplored in the neck.

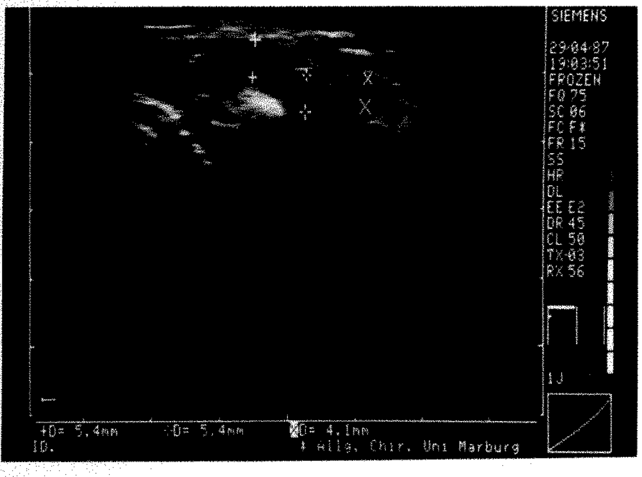

FIG. 1. Three particles of hyperplastic parathyroid tissue autografted in the forearm demonstrated by sonography.

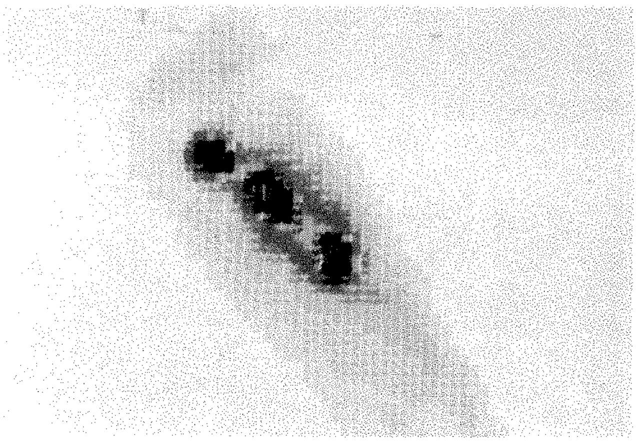

FIG. 2. Thallium scan of a hyperplastic autograft in recurrent renal HPT. Three hyperplastic particles are demonstrated.

During the resection of the grafted tissue, which was performed under local anesthesia on an outpatient basis, all palpable parathyroid nodules were removed, up to six nodules per patient. All hyperplastic nodules were surrounded by a capsule of connective tissue. An infiltrating growth in the surrounded muscle tissue was not observed. The nonpalpable part of the graft was left behind.

In seven patients serum calcium levels were normal after resection of the hyperplastic tissue in the arm. The follow-up ranged between 7 and 73 (median: 22) months. Only one patient is still hypercalcemic. The autograft is neither palpable nor detectable by sonography. Therefore, we conclude that HPT is caused by residual parathyroid tissue in the neck despite the removal of four glands.

The seven patients with graft-dependent recurrent HPT belong to a group of 117 patients who have been continuously followed in our department with a minimum follow-up of 1 year; 101 of these were autografted into the forearm. In the other patients subtotal parathyroidectomy was performed as part of a controlled trial that will be published later. The percentage of graft-dependent recurrent HPT in our material is, according to these figures, 7% (7 out of 101 patients). Histology of all tissue removed from the graft site revealed hyperplasia. In no case were signs of malignancy demonstrated.

Replantation of Autologous Cryopreserved Tissue

In 10 patients cryopreserved autologous tissue was grafted in a forearm muscle. The indication in four patients was aparathyroidism after reoperation in the neck without prior autotransplantation of fresh material and in six patients a nonadequate function of previously grafted fresh tissue after total parathyroidectomy requiring high dose treatment with calcium and vitamin D metabolites. The percentage of inadequate function of autografted fresh parathyroid tissue is therefore 6% (6 out of 101 patients).

The parathyroid tissue in the four patients without a fresh autograft was cryopreserved between 2 and 10 months, in the other patients between 2 and 42 months until reimplantation. In the first of these 10 patients 20 particles of 1 mm^3 were regrafted in the forearm muscle; 20% of the tissue was necrotic as demonstrated later. Sufficient graft function was noted after 21 months. In the other nine patients the percentage of necrotic tissue after freezing, cryopreservation, and thawing was examined prior to replantation by a previously published method.[6] It was between 1.7% and 50% (median: 20%). By compensating the necrosis rate using more than 20 particles depending on the degree of necrosis, the grafts functioned normally 3 to 7 months after replantation in eight patients. One patient in whom 50% of the tissue was necrotic received 40 particles. She discontinued her supplemental treatment several weeks thereafter, displaying low serum calcium levels. After 10 months she was normocalcemic.

Discussion

Our results show that most reoperations for secondary HPT must be performed because of hyperfunction of residual tissue in the neck or in the mediastinum. This corresponds with the experience of Dubost et al.[3] Since during reoperations most parathyroid glands were found at a normal site, an inadequate initial exploration (removal of less than four glands) must be assumed. It should be emphasized that in ten of the 18 patients the residual tissue was found in the mediastinum, mostly within the thymus, in five of these patients as a fifth gland after four glands had been removed previously. The removal of four parathyroid glands is therefore not equivalent to a sufficient parathyroidectomy in all patients.

According to Wang, 5–6% of all patients have supernumerary glands that are almost always found in the thymus.[7] In patients with secondary HPT these glands may be smaller than the other four and may secrete only a smaller amount of parathyroid hormone compared to the glands removed. Postoperatively due to the continuous stimulation of growth caused by renal failure, they can increase in size and cause recurrence.

We hope to reduce the number of reoperations if this experience can be part of a standardized initial operation. Together with the neck exploration and the removal of four glands that are usually found there, at least both thymic tongues or the whole thymus on both sides should be resected. This is also recommended by Diethelm.[8] This thymectomy should always be performed if one or both lower glands are not found in the neck.

Care should also be taken not to open the parathyroid capsule during exploration because this can lead to an inadvertently performed autotransplantation including a possible later recurrence of secondary HPT. Fresh parathyroid tissue should only be autografted in primary procedures or in reoperations if at least four histologically proven parathyroid glands and the thymic tongues have been removed. If not, autotransplantation should be cancelled and the tissue must be cryopreserved for possible deferred autografting.

Hyperfunction of the autograft in the forearm was the second most common reason for reoperations. All graft-dependent recurrences occurred after autotransplantation of fresh tissue and led to symptomatic disease and reoperation after a minimum of 32 months. In an individual patient with persistence or recurrence of secondary HPT after total parathyroidectomy and autotransplantation it is difficult to localize the source of hormone excess, namely, to differentiate whether it is in the neck or at the forearm. In our experience, simple procedures like palpation, sonography, and in some cases thallium scan can be helpful. They display enlarged parathyroid tissue within the muscle tissue. The parathyroid hormone determination in the blood, draining the graft bearing arm *versus* the contralateral arm, was not successful. One possible reason for this failure is the high level of parathyroid hormone in the systemic blood that can disguise a hormone gradient. The determinations in patients with a normal graft function show better results in the presence of generally lower systemic levels than were found in our patients.[9,10]

It is surprising that only a maximum of 6 of 20 autografted particles were enlarged. We also discovered parathyroid tissue particles of normal size during exploration of the graft site. We therefore do not agree with Dubost et al.,[2] who recommend the excision of the whole autograft. We excise only the palpable or visible hyperplastic nodules since this procedure led to a normal serum calcium in the majority of our patients. Permanent postoperative hypoparathyroidism is a severe complication after parathyroid surgery. It can be avoided by a permanent medication with calcium and vitamin D metabolites or by autotransplantation of cryopreserved tissue.

The operative alternative avoids the medication, which is sometimes difficult to manage. If the autografted tissue functions, it allows a normal calcium and phosphate metabolism and remineralization of bone.[11] Since permanent postoperative hypoparathyroidism can occur after total parathyroidectomy or after reoperations for recurrent or persistent HPT, cryopreservation should be performed after all these operations even if the majority of the patients will not need the cryopreserved tissue later. In our experience all patients regrafted by autologous cryopreserved tissue had a normal graft function after compensation of the necrosis rate of the cryopreserved tissue by grafting a larger amount of tissue.[6,11] A simple method for cryopreservation developed by us can lead to a wider use of this method in parathyroid surgery.[11]

The Limitations of Diagnosis of Carotid Occlusion by Doppler Ultrasound

NATAN M. BORNSTEIN, M.D., ZLATKO G. BELOEV, M.D., and JOHN W. NORRIS, M.D. F.R.C.P.

Duplex scanning has been advocated as an acceptable alternative to angiography in the preoperative evaluation of carotid artery stenosis. To evaluate the accuracy of carotid Doppler in differentiating severe carotid stenosis from occlusion, we compared the results of angiography with duplex scanning in 124 carotid arteries (62 patients) and with continuous-wave Doppler in 662 carotid arteries (331 patients). The specificity was 95–99%, sensitivity was 86–96%, and accuracy was 95–98%. Duplex scanning wrongly identified occlusion in four arteries and failed to detect occlusion in one artery. In making decisions prior to carotid endarterectomy, even infrequent errors are unacceptable. We recommend angiography of all surgical candidates with apparent severe stenosis when the internal carotid artery cannot be clearly identified on duplex, or to distinguish apparent occlusion from undetectably low blood flow.

From the Stroke Research Unit, Department of Neurosciences, Sunnybrook Medical Centre, University of Toronto, Toronto, Ontario, Canada

DISTINGUISHING BETWEEN severe carotid stenosis and occlusion is critical since it determines the prognosis and management of the patient. Carotid endarterectomy is a well-established and widely accepted therapy in patients with symptomatic carotid stenosis, but it is rarely worthwhile to attempt reconstructive surgery on occluded arteries.[1] Angiography, the *gold standard* for evaluating carotid disease, is the only way at present to distinguish this difference. An accurate, noninvasive diagnostic method is needed to avoid the hazards of angiography.[2,3] Some authors suggest that carotid Doppler can substitute for angiography in selected patients.[4–6]

Doppler sonography and digital subtraction angiography have become accepted methods of evaluating extracranial carotid disease.[7–13] Digital subtraction angiography involves the hazards of injected contrast media,[14] while ultrasound methods are without risk. We compared continuous-wave and duplex scanning with conventional and digital subtraction angiography to assess the accuracy of these techniques in detecting occlusion of the internal carotid artery and to determine whether duplex scanning is superior to continuous-wave Doppler.

Materials and Methods

Over an 18-month period (January 1, 1985 to June 30, 1986) all consecutive patients found to have one occluded carotid artery on Doppler scanning and who were referred for cerebral angiography, were analyzed retrospectively. Continuous-wave Doppler (Carolina Medical Electronics Dopscan Plus 1060 [Carolina Medical Electronics, King, NC], with spectral analysis and periorbital directional Doppler, with B-mode imaging and single-gate pulsed Doppler) was compared with angiography in an additional 331 patients. Ultrasonographic examinations were performed by two experienced technicians, with the patient lying supine and a 5-MHz probe applied to the extended neck at a 60-degree angle to the sagittal plane. Tape-recorded studies were interpreted by one of the study physicians without knowledge of the angiographic findings.

The ultrasonographic criteria for occlusion were a combination of: (1) failure to detect a flow signal from the internal carotid artery with continuous-wave Doppler; (2) asonic artery on pulsed-wave Doppler associated with plaque seen with B-mode imaging and longitudinal pulsation of the artery walls; and (3) reversed flow in the ophthalmic, frontal, or supraorbital arteries.

Carotid biplanar angiograms were interpreted by neuroradiologists who had no knowledge of the results of the sonographic evaluation.

TABLE 1. *Accuracy of Duplex Scanning Compared with Angiography in Detecting Carotid Occlusion in 124 Arteries**

Duplex Scanning	Angiography		
	Occlusion	Nonocclusion	Total
Occlusion	24	4	28
Nonocclusion	1	95	96
Total	25	99	124

* Sensitivity = 96%, specificity = 95%, postive predictive value = 86%, negative predictive value = 99%.

Results

Sixty-two consecutive patients with one occluded artery demonstrated by duplex scanning (50 men and 12 women, mean age 69 years) had either digital-subtraction or conventional angiography. Both duplex scanning and angiography detected occlusion of 24 arteries, but duplex scanning wrongly identified occlusion in four arteries (false-positive) and failed to detect occlusion in one artery (false-negative), resulting in a sensitivity of 96%, specificity of 95% and accuracy of 95% (Table 1).

When continuous-wave Doppler results in 331 patients (662 arteries) were compared with angiography, Doppler incorrectly diagnosed occlusion in seven arteries and failed to detect occlusion in another seven arteries. The sensitivity was 86%, specificity 99%, and accuracy 98% (Table 2).

Discussion

The reported accuracy of duplex ultrasound in predicting the degree of stenosis varies from 80–97%,[9,11,15–17] but no study yet has specifically evaluated its diagnostic accuracy in carotid occlusion. Too few occluded arteries were identified in published studies to warrant separate statistical analysis.[11,15–24] Levien et al.[25] evaluated a variety of noninvasive tests (including continuous-wave but not duplex ultrasound) in the diagnosis of carotid occlusion and found a sensitivity of 70% and specificity of 98%. Pooling all available data[11,15–24] on duplex scanning over the last five years, results are very similar to ours (Table 3).

The low frequency of missed diagnoses in our study (2–5%) indicates that continuous-wave and duplex ultrasound are both relatively reliable in detecting occlusion, but even infrequent false-negative results are disturbing, since such patients may undergo unnecessary surgery. More significantly, severe stenosis (95–99%) was found at angiography in four patients who had apparent carotid occlusion on duplex scanning. If these patients were assessed only by Doppler, they would remain unoperated and at high risk of stroke.

TABLE 2. *Accuracy of Continuous-wave Scanning Compared with Angiography in Detecting Carotid Occlusion in 662 Carotid Arteries**

Continuous-wave Scanning	Angiography		
	Occlusion	Nonocclusion	Total
Occlusion	42	7	49
Nonocclusion	7	606	613
Total	49	613	662

* Sensitivity = 86%, specificity = 99%, positive predictive value = 86%, negative predictive value = 99%.

TABLE 3. *Analysis of Pooled Data*[11,15–24] *Comparing Duplex Scanning with Angiography in Detecting Carotid Occlusion in 2095 Arteries**

Duplex Scanning	Angiography		
	Occlusion	Nonocclusion	Total
Occlusion	211	26	237
Nonocclusion	37	1821	1858
Total	248	1847	2095

* Sensitivity = 85%, specificity = 98%, positive predictive value = 89%, negative predictive value = 99%.

In two cases of apparent occlusion on duplex scanning, the external carotid artery was superimposed on the internal carotid artery so they could not be differentiated. A falsely positive temporal *tapping test*[26] occurred in another case when the vibrations were transmitted down the external and up the internal carotid artery. In a fourth case, the angiogram revealed a vascular anomaly, with a common origin of the right innominate and left carotid arteries so duplex scanning could not image the left carotid system. In three of these cases of apparent occlusion the artery was asonic but periorbital flow was normal. Of the seven instances of false-positive diagnoses on continuous-wave scanning, four were due to severe stenosis, where blood flow was so reduced as to be undetectable, and in one case extensive calcification masked severe stenosis.

Ultrasound evaluation, without angiographic confirmation, has been advocated as the basis for carotid surgery for some patients.[4–6] This is probably acceptable for patients with tight stenosis when the internal carotid artery is clearly identified on duplex imaging. When appearances suggest occlusion, angiography is needed to determine whether blood flow is so reduced as to be undetectable by Doppler or truly absent.

Acknowledgments

We thank Lorraine Chadwick and Susan Corrigan for performing the Doppler examinations, Cecily Ziliotto for managing the data, and Barbara Huth for editing the manuscript.

The Improving Long-term Outlook for Patients over 70 Years of Age with Abdominal Aortic Aneurysms

EUGENE F. BERNSTEIN, M.D., PH.D., RALPH B. DILLEY, M.D., and HARRY F. RANDOLPH III, P.A.-C.

During the past decade, selective criteria for elective surgery for abdominal aortic aneurysms have been refined based on natural history and aneurysm expansion information. Using these criteria, contemporary preoperative preparation and newer intraoperative technical adjuncts, 123 consecutive patients underwent elective resection with 1 death (mortality rate: 0.8%). These include all patients operated on with both elective and urgent aneurysms at this institution since 1978, with the exception of those with frank rupture. Most importantly, however, the 5-year life-table survival of all of these patients (average age: 71.3 years, range 46–96 yr) was 72%, including both hospital and late mortality rates. More than half of the patients were over 70 years old (78 cases), with no hospital deaths and a 5-year life-table survival probability of 67%. For those under 70 years of age at the time of operation, the 5-year life-table probability of survival was 79%. We believe that these accomplishments were a direct result of an aggressive policy of screening for and selectively treating coronary disease and carotid stenosis preoperatively and the utilization of such intraoperative adjuncts as routine Swan-Ganz monitoring, autologous blood transfusion, the cell saver, and the frequent use of the tube grafting (50%). Thus, with proper selection, the outlook for the patient over 70 years old with an elective abdominal aortic aneurysm resection now approaches that of the normal population (67% *vs.* 69%).

REFINED DIAGNOSTIC TECHNIQUES for infrarenal abdominal aortic aneurysms have made it possible to identify patients at risk from this condition at an earlier stage, and permit a more careful evaluation of aneurysm size and associated risk factors.[1,2] Long-term follow-up of unoperated patients with small abdominal aortic aneurysms by ultrasound, and more recently by CT scanning, has determined the mean expansion rate for aneurysms under 6 cm in size to be 4 mm/yr.[2] Thus, surgical selection has improved parallel to advancing surgical management techniques for such patients. As a result, the mortality rate associated with elective surgery for abdominal aortic aneurysms has decreased significantly each of the last several decades.[3–7] More important, however, has been the effect of improvement in diagnosis, selection, and management on the longevity of patients with this condition.

From the Division of Thoracic and Vascular Surgery, Scripps Clinic and Research Foundation, La Jolla, California

The opening of the Green Hospital of Scripps Clinic in 1978 permitted the acquisition of data regarding all patients operated on in this center by two surgeons (E.F.B. and R.B.D.) with a single protocol since the inception of surgical activity. This report summarizes our initial experience with elective surgery for abdominal aortic aneurysm at the Scripps Clinic.

Materials and Methods

One-hundred twenty-three consecutive patients were subjected to elective surgery for abdominal aortic aneurysms from January 1, 1978 through December 1985. Their charts were surveyed for data regarding aneurysm size, general physical condition, presence of associated risk factors, and prior cardiovascular surgery. In addition, the preoperative angiograms were reviewed for documentation of additional para-aneurysmal disease, and particularly for unusual renal arterial anatomy, renal artery stenoses, and anomalies. Operative reports were abstracted to obtain data regarding aneurysm size, anesthetic time, operative time, aortic cross-clamp time, type of graft implanted, utilization of the cell saver, and operative blood loss. Information was also obtained regarding operative mortality and hospital morbidity rates, and all data were categorized by patient age. All surviving patients were contacted to determine their current health status, and an effort was made to deter-

mine the time and cause of death of all patients who died. Such information was obtained by review of the patients' charts, contacting the Bureau of Vital Statistics of San Diego County, and direct written or verbal contact with the patient, the family or personal physician. Every effort was made to confirm the final cause of death from autopsy or death certificate information.

All data were entered on a VAX 11/750 computer using CLINFO software for clinical research management analysis. Life-table analyses were performed according to the procedure of Kaplan and Meier[8] and Gehan.[9]

Selection for Surgery

General criteria for operative intervention included all aneurysms of 5 cm or more in largest transverse diameter in good risk patients. Noninvasive tests were routinely used to confirm the diagnosis and to estimate aneurysm size. During the earlier years of the study, ultrasound was the predominant method of noninvasive examination, but more recently CT scanning has been used liberally and is now considered the diagnostic technique of choice. All patients with symptomatic aneurysms were operated on, regardless of patient's age or aneurysm size. Included in these data are all patients with urgent procedures in whom the aneurysm was discovered to be intact at the time of surgery.

Questionable operative indications. Contraindications to surgery included a myocardial infarction within 3 months, the presence of intractable congestive heart failure, dyspnea at rest, permanent significant residual neurologic deficit from stroke, or advanced renal disease with a creatinine of 3 or greater. In addition, the presence of other terminal diseases with a life expectancy of less than 3 years was considered a contraindication to elective surgery. Poor risk patients with small asymptomatic abdominal aneurysms (less than 6 cm) were followed routinely at 3-month intervals with echography or CT scanning and were operated upon if they became symptomatic or if the aneurysm reached a size of 6 cm. In addition, the rapid enlargement of an aneurysm (greater than 1 cm in a year or less) in a poor risk patient was considered an indication for surgery.

Preoperative routine. All elective aneurysm patients were subjected to treadmill coronary stress testing and cardiologic consultation. A positive stress test was an indication for coronary angiography, and angiographic evidence of severe coronary disease such as greater than 90% stenosis of the left main, right main, or left anterior descending coronary arteries, even if asymptomatic, was considered an indication for preliminary coronary bypass. In addition, a noninvasive carotid duplex scan was performed on any patient in whom there was a history of a cerebrovascular event or evidence of a carotid bruit. Stenoses greater than 80% by diameter were treated by staged carotid endarterectomy. During the past year, patients were informed about and encouraged to participate in an autologous blood donation program in which 1 or 2 units of blood were donated during the 2 weeks prior to admission for aneurysmectomy. A minimum period of 6 days was required between the last blood donation and admission for elective surgery.

On the day of admission all patients were subjected to formal contrast aortography to define the status of their renal and visceral vessels, the proximal extent of aneurysms suspicious for suprarenal involvement, and the extent of distal iliac disease. A Swan-Ganz catheter was placed and the patient transferred to the intensive care unit for hydration and cardiac monitoring the evening before surgery.

Current operative routine. All patients were monitored with both an intra-arterial line and the Swan-Ganz catheter. Cefazolin was administered to all patients preoperatively. In addition, more recently intrathecal morphine was injected just after anesthetic induction to minimize postoperative pain. The abdominal wall was prepared with Betadine and covered with a Vi-drape. All patients were operated on through a vertical midline transperitoneal incision. The Gomez self-retaining retractor greatly facilitated exposure of the aneurysm and virtually eliminated the need for a second assistant. Proximal dissection was minimized and limited to the area of the neck of the aneurysm. Further dissection usually was limited to the common iliac vessels. The patient was systemically administered heparin 5000 U I.V. Occlusion of the common iliac arteries was generally performed first to prevent atheromatous embolization, followed by proximal aortic clamping with Wylie hypogastric artery clamps, which offer little interference to the operating surgeon. Preclotted knitted Dacron prostheses were used routinely. The Hemonetics Cell Saver (Haemonetics Corp., Braintree, MA) was utilized during the last 3 years on all elective cases. Tube grafts were placed for reconstruction whenever possible. Prolene was used for all vascular anastomoses. Following coverage of the Dacron graft by a retroperitoneal closure in two layers, the area of dissection and graft implantation was irrigated with a Kanamycin and Bacitracin solution.

Details of the special operative techniques required to deal with simultaneous suprarenal extension, hypogastric aneurysms, horseshoe kidney, accessory renal arteries, renal stenosis, mesenteric vascular insufficiency, inflammatory aneurysms, and other complications are beyond the scope of this article, but we have followed conventionally accepted approaches to these situations.

Postoperative routine care included 3 to 4 days in the intensive care unit. Fiberoptic bronchoscopy was used

Values are given as percentages.

liberally for atelectasis or retained bronchial secretions. The Swan-Ganz catheter and arterial line were generally removed on the first or second postoperative day as was the Foley catheter. The nasogastric tube was retained until full evidence of intestinal function was present. Prolonged nasal oxygen was monitored by room air blood gas analyses and usually used for 5 to 6 days. Prolonged hospital stays averaging 10 days were routine. Following discharge, all patients were entered in the Vascular Registry, and follow-up was requested at 1, 3, 6, and 12 months and then on an annual basis.

Patient Demographic and Risk Factors

One-hundred twenty-three patients were operated on during the review period; 102 (82.9%) were males and the mean age was 71.4 years (range; 46–93 yr); 102 of the patients were smokers (82.9%).

Pertinent risk factors are summarized in Table 1, and include hypertension in 54.9% and severe respiratory, cardiac, and/or renal disease in 18–21%. Seven patients (5.7%) had been subjected to prior coronary artery bypass; 6 (4.9%) had a previous history of stroke; and 5 had prior carotid endarterectomy (4.1%). Conditions requiring additional or modified surgery included inflammatory aneurysm (1), severe renal artery stenosis causing hypertension (1), horseshoe kidney (2), and inferior mesenteric artery reimplantation (1). None of the aneurysms extended above the renal arteries, requiring suprarenal resection.

Operative Factors

Mean aneurysm size at the time of surgery was 5.8 cm (range; 3–11). Anesthetic time averaged 3.5 hours (range: 2–6.3) and mean operative time was 2.4 hours (range: 1–5). Aortic cross-clamp time averaged 48 minutes. Tube grafts were employed in 50% of the patients and bifurcation grafts in the remainder. There was no difference in the mean aneurysm size between those in whom bifurcation grafts were necessary or where tube grafts could be used (Table 2). However, cross-clamp time was decreased from 52 to 40 minutes when tube grafts were inserted ($p < 0.001$). In addition, mean operating time was decreased from 2.5 to 2.2 hours.

Cell saver. Seventy-five patients were operated on prior to the initiation of routine cell saver use with an average blood loss of 1582 mL, and an average replacement of 4.1 U of bank blood. Since institution of the use of the cell saver on a routine basis, 47 additional patients have been operated on with a mean blood loss of 1087 mL and an average return of 3.2 U of cell saver blood (560 mL), which decreased the requirement for bank blood from 4.1 to 2.0 U.

Operative mortality and morbidity rates. There was one operative death within the hospital or 30-day postoperative course in the 123 consecutive patients in this series (0.8%). Operative morbidity rate is summarized in Table 3 and indicates a predominance of pulmonary, renal, peripheral vascular, and thromboembolic problems. Only one cardiac complication occurred (myocardial infarction), and there were no associated strokes. An analysis of morbidity rates by age group indicated only a modest increase after the age of 65.

Survival. The overall life-table probability of survival for all patients in this series at 5 years was 72%, including the operative mortality. For those patients who were hypertensive it was 73%. Patients with a prior history of myocardial infarction had a significantly reduced probability of 5-year survival at 51%, in contrast to those with a prior coronary artery bypass procedure who had a 100% likelihood of 5-year survival.

For the fifty-six patients less than 70 years of age the probability of surviving 5 years was 79%. For those between 70 and 79 years of age (N = 47) the probability of surviving 5 years was 67% and for those patients 80 years or older (N = 20) the probability was 66%. The comparative 5-year survival probability between those over and under 70 years of age is documented in Figure 1 and Table 4, and shows essentially no difference for

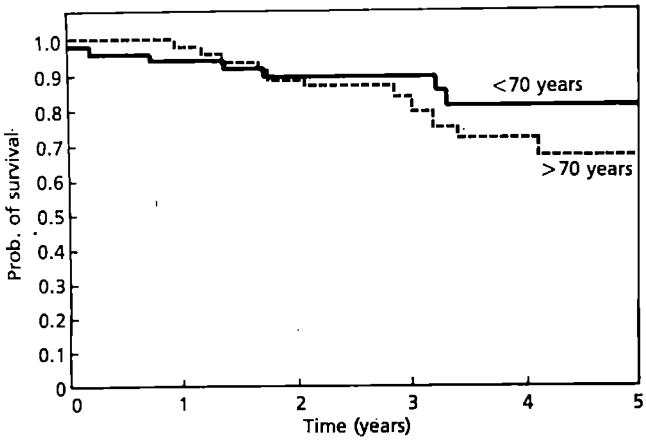

FIG. 1. Life-table analysis of survival following elective abdominal aortic aneurysm surgery.

the first 3 years and no significant difference at 5 years. Table 5 compares the current series with the recently published data of Crawford et al.[5] and of Hollier et al.[10] In all of these studies, the elective operative mortality rate for aneurysm surgery is in the range of 2% or less, and the likelihood of surviving 5 years following surgery is approaching that of the general population, which is 80% for an age- and sex-adjusted group. Most significant, however, is the increase in survival for the patient group over the age of 70. The report by Crawford et al.,[5] which includes Crawford's entire 25-year experience, includes patients treated in a much earlier era, with a 43% probability of 5-year survival for patients over 70, which must be regarded as representative of very good results during the time span reported. This impression is also confirmed by the data of Johnson et al.,[7] which includes the time span since 1952. However, the recent Mayo Clinic publications,[3,4,10] as well as our own, indicate a substantial increase in the likelihood of survival for those patients over 70, which closely approaches the survival of the general population with a similar age and sex distribution.

Discussion

Improvement in the care of patients with abdominal aortic aneurysms during the 35 years since the first replacement procedures were introduced has been based on progress in the following areas:

1. *Early diagnosis.* Increased suspicion, and the ready availability of relatively inexpensive and extremely accurate noninvasive methods have permitted diagnosis at an earlier stage since the introduction of ultrasound in 1970 and CT scanning in 1980.[1,2] Both modalities are essentially 100% sensitive in the detection and accurate diagnosis of the disease, and are within 2–3 mm of operative size estimates. Thus, 80% of the aneurysms detected in the extensive UCSD series[2] during the past 15 years were 6 cm or less. Therefore, the clinician

73–84	3	2	1	0	1.0	0.620
85–96	1	1	0	0	—	—

is more frequently faced with a patient with a smaller asymptomatic aneurysm.

2. *Thorough cardiovascular evaluation.* Routine cardiac stress testing and frequent or routine cerebrovascular scanning has markedly reduced the incidence of cardiac and neurologic complications, which used to be most feared in elective aneurysm surgery. The identification of severe coronary or carotid arterial disease has become an indication for prior revascularization of these vessels. However, routine coronary angiography, as advocated by Hertzer[6] and Hertzer et al.[11] does not appear to be necessary or appropriate in this setting.

3. *Extensive preoperative preparation.* Preoperative evaluations of pulmonary function and renal disease, formal aortography, and the routine placement of a preoperative Swan-Ganz catheter permits maximizing prophylactic and early therapeutic management of potentially serious complications. We have followed the suggestions of Ruby et al.[12] and Whittemore et al.[13] throughout this series and firmly believe they have been very important adjuncts in the intraoperative and early postoperative management of many of these patients.

4. *Expeditious surgery.* The availability of the Gomez self-retaining retractor, minimizing the need for assistance and erratic retraction, routine use of the cell saver, administration of autologous blood, and minimal dissection have decreased blood loss and expedited surgery. The average operating time of 2.5 hours in an institution heavily committed to a vascular fellowship training program documents the resulting advantages in patient care. Alternative procedures, such as induced aneurysm thrombosis and peripheral bypass, as advocated by Leather et al.[14] do not seem necessary as emphasized by Schwartz et al.,[15] since the operative morbidity rate for elective resection can be decreased to under 1% despite the presence of serious multisystem compromise and advanced age in many patients.

5. *Aggressive postoperative care.* Problems of hemodynamic stability, respiratory function and renal function are pursued with vigor during the early postoperative period.

6. *Antibiotic prophylaxis.* The routine use of preoperative, intraoperative, local operative, and postoperative antibiotics appears to have minimized wound and other infectious problems. In the entire series there has been no instance of graft infection or of serious wound infection.

7. *Regular or routine postoperative follow-up.* The computerized vascular registry permits identification of patients' current status on a continuing basis. Patients who have not returned for routine follow-up visits are contacted regarding their current status in a regularized fashion. This permits periodic surveys of the late complications of surgical treatment and allows monitoring and continuing care of associated medical problems. In addition, it provides the surgeon with a continuing stream of information regarding the surgeon's own experience, problems, and late results.

Conclusions

A consecutive series of 123 patients with abdominal aortic aneurysms were subjected to elective or urgent surgery with a mortality rate of 0.8% and overall 5-year survival rate of 72%. These results attest to improvements in our ability to select patients for elective surgery and perform such procedures with a low risk rate. In addition, the earlier diagnosis of these lesions simplifies the surgical approach, permitting the use of tube grafts in 50% of the patients. No late complications of iliac aneurysm enlargement were detected in this series as a result of this policy. Elective aneurysm surgery is now capable of achieving late survival rates approaching those of the normal population despite the presence of significant concomitant cardiovascular, pulmonary, and renal disease.

CLASSIFIED AD SECTION

Classified advertising is available in **ANNALS OF SURGERY** for those recruiting personnel or interested in obtaining positions. Display space also is available for those desiring greater visibility or more space for their message.

Classified ad copy, like other advertising copy, will be reviewed for approval prior to publication.

Classified Rates: $9.00 per line or fraction of line. The average line will be 40 characters.

Box Numbers: Replies may be directed via Box # to J.B. Lippincott Company, at an extra charge per insertion of $6.50 to cover handling costs in forwarding such replies to the advertiser.

How to Order: Send typewritten text copy for the ad with remittance in full to:

ANNALS OF SURGERY
c/o J.B. Lippincott Company
Attn: Janet Eagan
East Washington Square
Philadelphia, Pa. 19105
(215) 238-4215

Deadline: Copy received by the 15th of month will run in the second following month's issue, e.g. November 15th for January issue. Ads received after the 15th will run in the next available issue.

BC/BE General/Vascular surgeon to join two surgeons in multi-specialty group practice, West Coast Florida, very generous salary and benefits package leading to partnership. Reply to **Box ANN3A, J.B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

BC/BE General Surgeon to associate with two active internists in NE Wisconsin. New clinic and modern hospital with state-of-the-art ICU. **Box ANN3B, J.B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

BURN FELLOWSHIP—The New York Hospital-Cornell Medical Center Burn Center is a modern burn treatment facility with 24 intensive care beds and annual admissions of 850 in-patients and 3,000 out-patients. During the year's experience, the Fellow will be responsible for the surgical critical care of all burned patients, for house officer education, and for participation in original and on-going clinical research protocols. The Burn Center is the recipient of an NIH Burn Research Center Grant and supports comprehensive laboratories with state-of-the-art instrumentation and active investigators in the fields of wound healing, immunology, metabolism, nutrition, and cardiopulmonary response to injury. An additional year in the laboratory may be elected by the Fellow. Candidates preferably should be Board eligible in General Surgery, but we will strongly consider academically oriented senior surgical residents from university programs incorporating the Fellowship as part of their training programs. Send inquiries to: **Cleon W. Goodwin, M.D., New York Hospital-Cornell Medical Center, 525 East 68th Street, Room L704, New York, New York 10021.** Cornell University is an Equal Opportunity/Affirmative Action Employer.

ALL SURGICAL SPECIALTIES, NATIONWIDE. Excellent Quality of Life and Compensation. Dr. Len Goodman, SMA, PO Box 25786, Charlotte, NC 28229. 704-536-2527.

BOULDER, COLORADO: Thirty-five physician multispecialty group seeking Board Eligible/Board Certified General Surgeon with interest in Thoracic/Vascular surgery. Interested please send CV to **John Day, M.D., Boulder Medical Center, P.C., 2750 Broadway, Boulder, CO 80302.**

CHAIRMAN, DEPARTMENT OF SURGERY: Medical University of South Carolina, Charleston, SC. A major teaching department seeks a qualified candidate to direct a department that consists of divisions of cardiovascular surgery, general surgery, plastic surgery and peripheral vascular surgery. Send CV to **Charles P. Darby, M.D., MUSC, Children's Hospital, 171 Ashley Avenue, Charleston, SC 29425.**

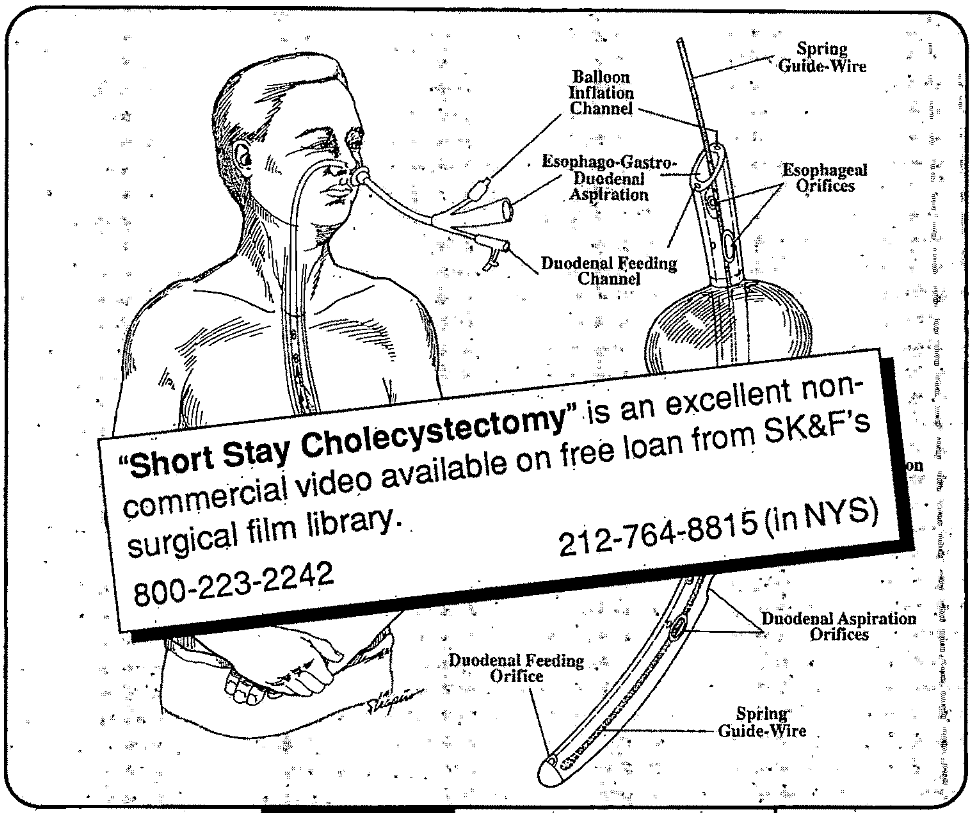
General Surgeon—(BC/BE) to join busy 35 physician multispecialty group in Northeastern Massachusetts 35 miles from Boston. Excellent first year salary guaranteed with eventual association. Please send C.V. and references to **Leonard Block, M.D., Medical Associates, 199 Chelmsford Street, Chelmsford, MA 01824 - (617) 256-6511.**

KANSAS: We are seeking a general surgeon interested in a full-time private practice opportunity in the greater Kansas City area. For further information, please send current CV to **Linda Smith, Central Business Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri 64111; or call 1-800-821-5147 or 818-561-1025.**

SURGICAL ONCOLOGY, ASSISTANT PROFESSOR—Department of Surgery, Case Western Reserve University and Cleveland Metropolitan General Hospital are recruiting another individual with an academic commitment to oncology to join an established group. Basic research experience is essential. Funding and protected time available for scholarly activity. Case Western Reserve University and Cleveland Metropolitan General Hospital are equal opportunity, affirmative action employers. Women and minority candidates are encouraged to apply. Send curriculum vitae and two references to: **Anthony L. Imbembo, M.D., Director, Department of Surgery, Cleveland Metropolitan General Hospital, 3395 Scranton Road, Cleveland, Ohio 44109.**

SURGERY: TRAUMA—Board eligible surgeon to join full-time faculty in growing Trauma Program in a junior position; no fellowship required. Preference given to those completing General Surgery residency in June, 1988, and planning career in Trauma Surgery. Interested candidates contact: **Stanley Z. Trooskin, M.D., Chief, Division of Trauma Surgery, UMDNJ-Robert Wood Johnson Medical School, One Robert Wood Johnson Place, CN-19, New Brunswick, NJ 08903-0019.** An equal opportunity/affirmative action employer m/f/h/v.

Thoracic Surgeon experienced in adult cardiac, general thoracic and peripheral vascular surgery is needed to join 195 physician multispecialty prepaid group in Hawaii. Board certified associate. Excellent fringe benefits. Malpractice paid. Please direct curriculum vitae: **Hawaii Permanente Medical Group, Inc., 3288 Moanalua Road, Honolulu, HI 96819.** (AN EQUAL OPPORTUNITY EMPLOYER)



"Short Stay Cholecystectomy" is an excellent non-commercial video available on free loan from SK&F's surgical film library.

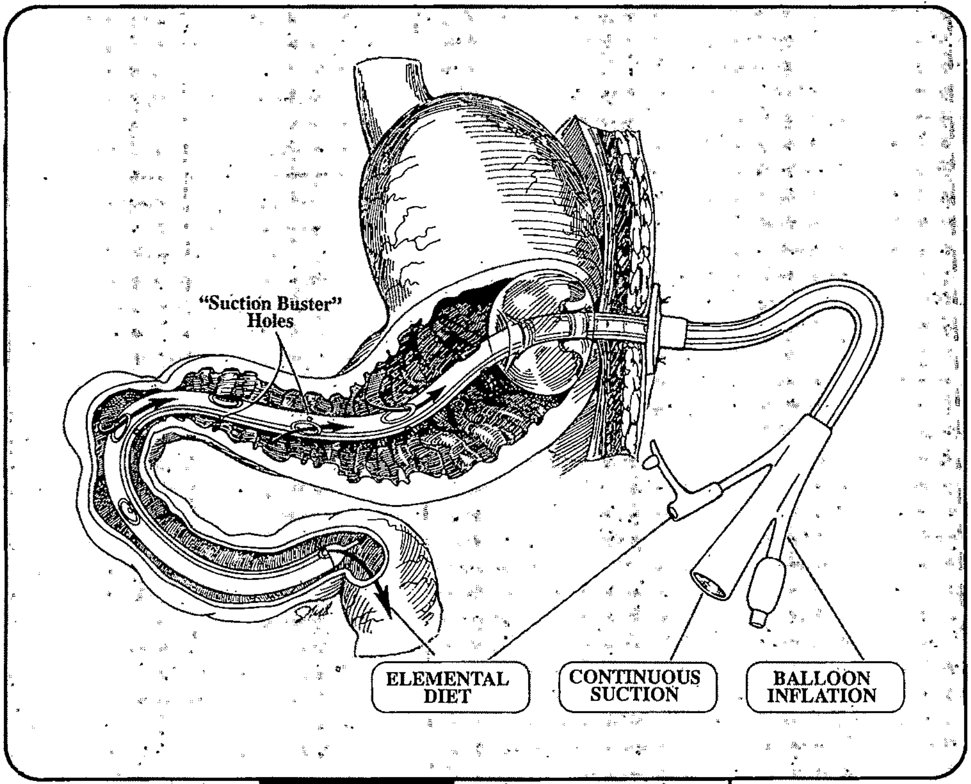
Moss® Nasal Tube-Mark IV

Esophageal/duodenal decompression is 12-14 times more efficient than gastric aspiration of alternative devices.* "Enteral hyperalimentation" begins immediately postop, with reported decreased sepsis, wound problems and markedly shortened L.O.S.*



Moss® Gastrostomy Tube

® Gerald Moss, PhD, MD, FACS

Patented

Moss®

Decompression--
Feeding Catheters

Mark IV is the most compact (#18 French), efficient, and occlusion resistant design since initially introduced in 1963. Its integral spring guide-wire makes it the most easily passed.

Distributed By:

Moss Tubes, Inc.
Box 296
W. Sand Lake, N.Y.
12196
(518) 674-3109

Made of #18 French biocompatable silicone for minimum trauma without sacrificing efficiency of performance.

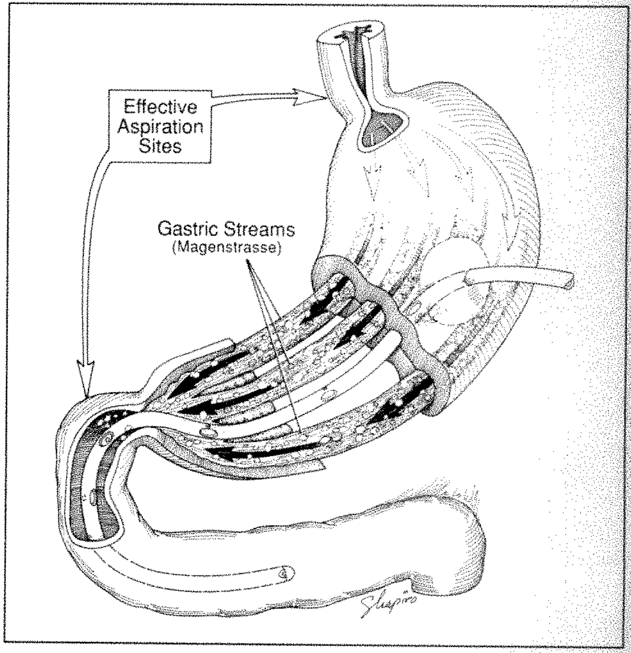
* Send for reprints documenting results from independent clinical centers.

INCOMPARABLE MOSS® TUBES ....

(but compare with other feeding-decompression tubes anyway.)

1. Decompression Site

Gastric suction alone cannot work! The stomach's longitudinal folds mimic parallel segments of intestine. Aspiration orifices may empty a single "Magenstrasse" (figure A). Most swallowed air avoids suction, and is propelled through the pylorus via adjacent channels. A clinical study of other N-G and G-tubes measured 32-42% inefficiency. *A toll booth in the center of a wide highway cannot collect from traffic in the outer lanes.*
Removal of air is most effective at constricted (single-file) sites. Measured efficiency increases 12-fold by adding aspiration within the adjacent esophagus and/or duodenum. And flowing duodenal digestive juices "self-cleanse" the tube of occluding mucus.

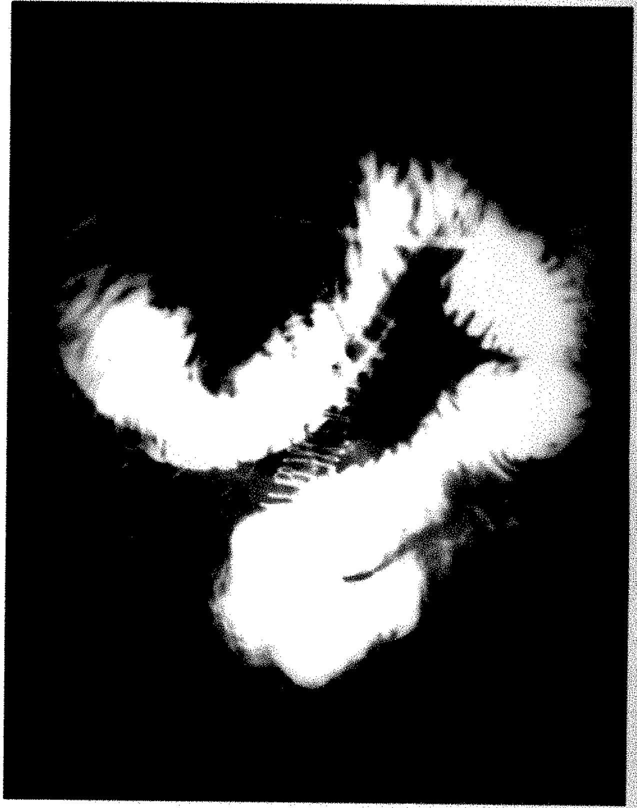


A. The functioning stomach subdivides into discrete"Magenstrasse". Any tube can only evacuate the single gastric stream within which it lies.

2. Feeding site

Gastric feeding risks distention and aspiration. **Jejunal** delivery bypasses 1-3 feet of proximal intestine, acting as a barrier to retrograde decompression. Aspiration of feedings is less likely, but remains a risk. Minimal initial infusion (starvation) is manditory initially.

The **Moss®G-Tube's duodenal** delivery site is the most effective. With proximal duodenal aspiration (patented), the initial distal feeding rate is unlimited. Clinical x-rays visualized removal of all excess feeding, with none reaching the stomach. (Fig. B) The full length of intestinal absorption is available immediately. Earliest "enteral hyperalimentation" is safely instituted within the recovery room. Positive nutritional balances are achieved, leading to enhanced sepsis resistance, accelerated wound healing and shorter L.O.S.



B. Study @ 5 minutes. Note effective removal of all excess barium flowing retrograde, none visualized to reach the stomach.

3. Aspiration Orifices

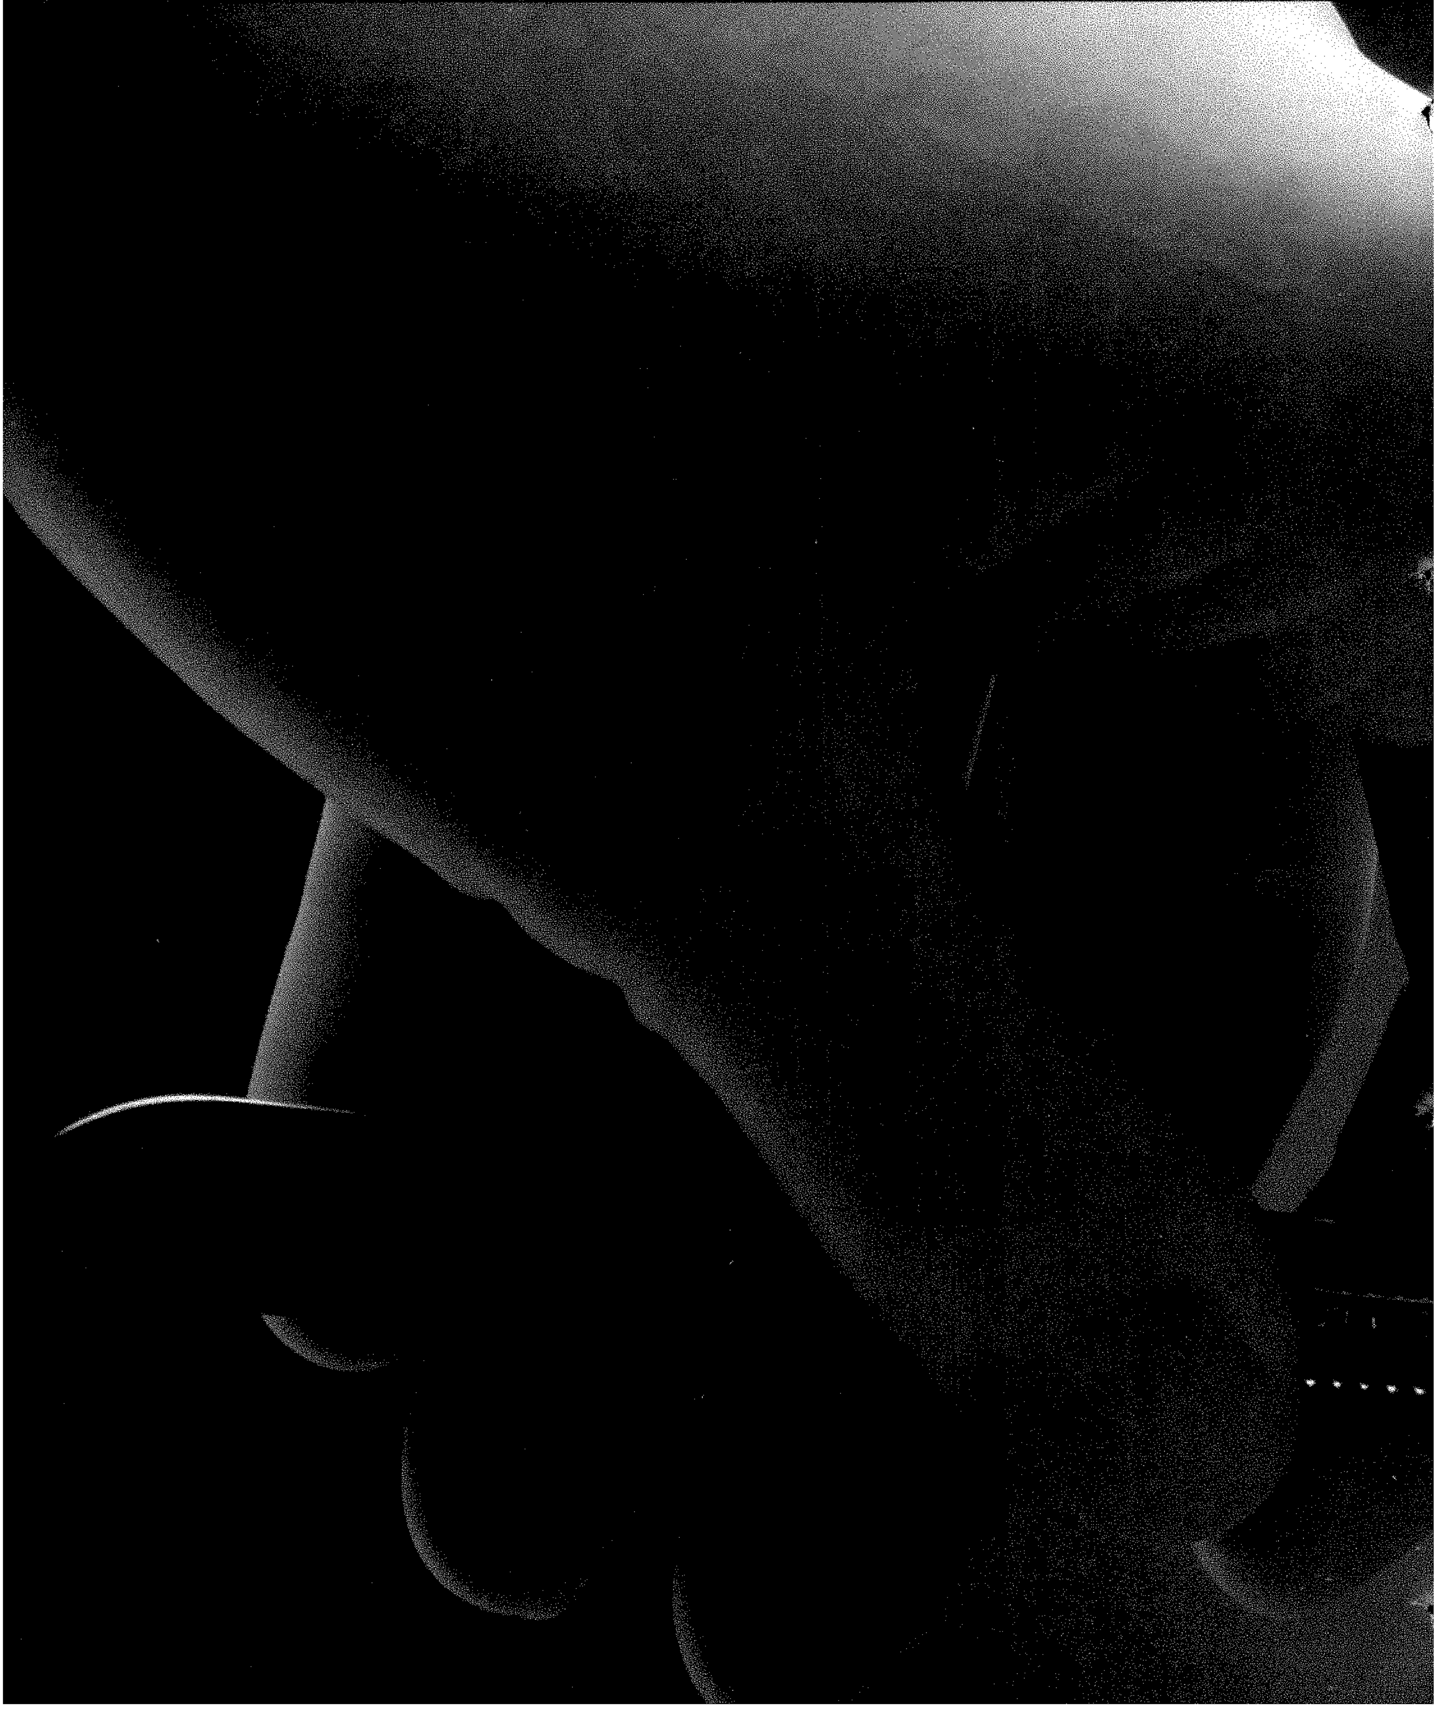
Uniformly sized orifices (**all others**) "suck in" mucosa to occlude the openings and stop decompression. Mucosal release then requires a null period (intermittant suction). Prograde air or retrograde feedings can be propelled accross and beyond the stomach, causing distention or aspiration.

By pairing each large orifice with a patented, smaller "suction buster"®opening (**Moss®G-tube**), continuous aspiration is maintained despite inadvertantly elevated suction.

4. Biomaterials

The **Moss®G-Tube** is **all silicone**, the accepted "gold standard" for optimum long term stability, tissue tolerance and biocompatibility.

DEFINING A NEW STANDA



D FOR EMPIRIC THERAPY

For Infection Following
*Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

☐ Anaerobic coverage of clindamycin or metronidazole plus

☐ Gram-negative coverage of an aminoglycoside plus

☐ Gram-positive coverage of cefazolin plus

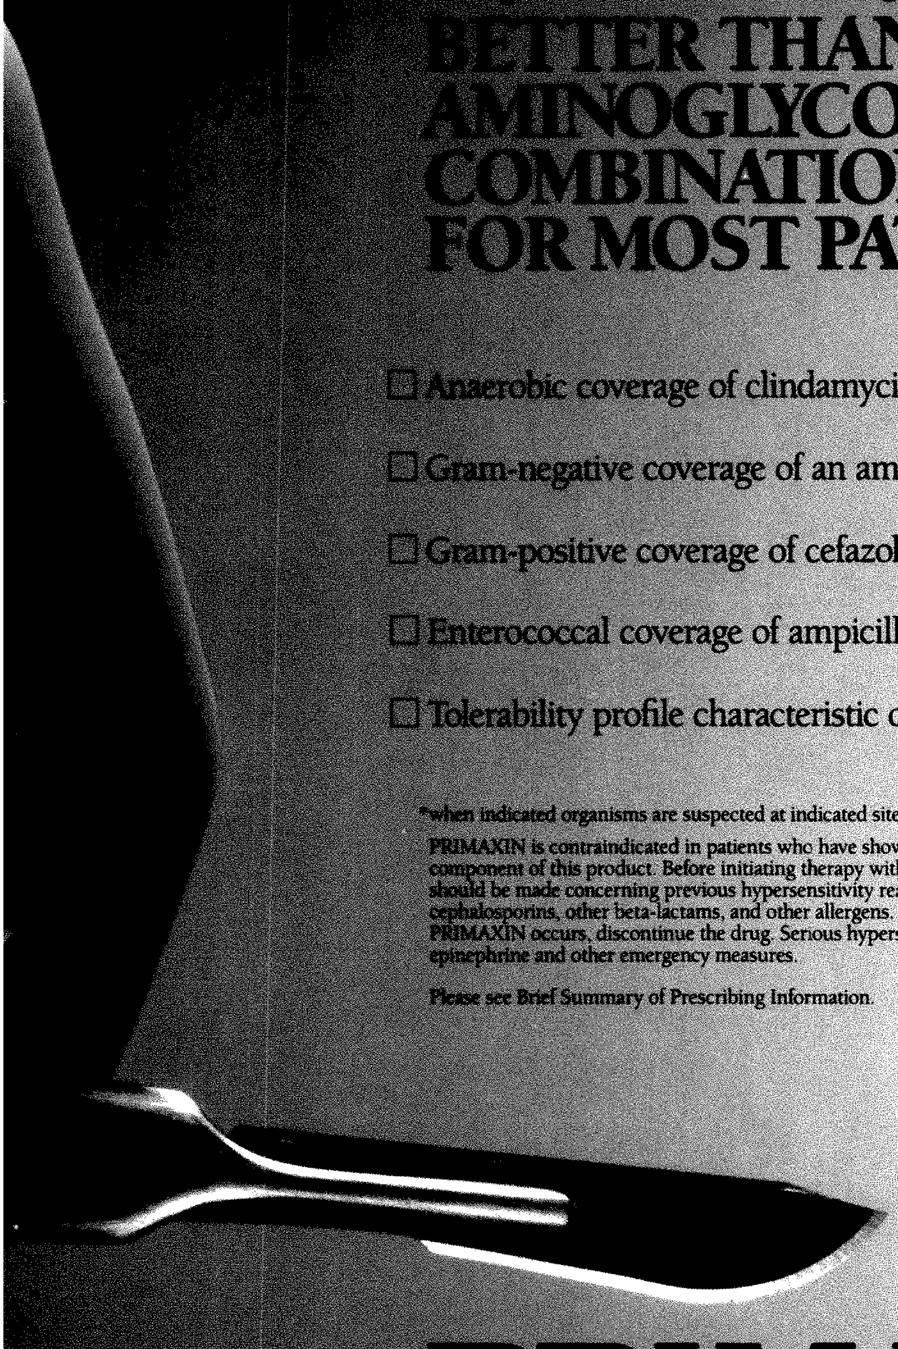
☐ Enterococcal coverage of ampicillin plus

☐ Tolerability profile characteristic of beta-lactam antibiotics

*when indicated organisms are suspected at indicated sites

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

Please see Brief Summary of Prescribing Information.



INTRAVENOUS
PRIMAXIN®
(Imipenem-Cilastatin Sodium|MSD)

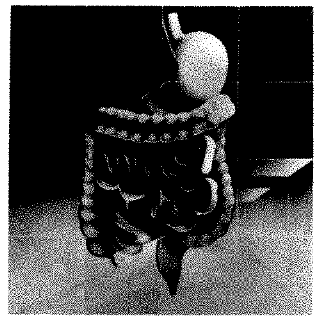
Copyright © 1988 by Merck & Co., Inc.

DEFINING A NEW STANDARD FOR EMPIRIC THERAPY

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium|MSD)



Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN,' CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of $\leq$5 mL/min/1.73 m^2 should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

- *Pregnancy*—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in non-pregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Renal*—oliguria/anuria, polyuria; *Skin*—erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage®[†] vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

The Acute Surgical Abdomen after Cardiac Surgery Involving Extracorporeal Circulation

ALEXANDER S. ROSEMURGY, M.D., EARL McALLISTER, M.D., and RICHARD C. KARL, M.D.

From 1972 through 1984, 7140 cardiac operations were performed at one university teaching hospital; they were reviewed to elucidate common factors in patients developing an acute surgical abdomen after cardiac surgery and extracorporeal circulation. Twenty-one patients (0.29%) developed an acute surgical abdomen in the period following cardiac surgery. The abdominal surgical complications were, in general, due to complications of peptic ulcer disease, decreased intestinal blood flow, and cholecystitis. There was no correlation between preoperative history, physical examination, cardiac function, laboratory data, and the subsequent development of an acute abdomen. Mortality rate, 24% after abdominal surgery, was increased with emergency cardiac operations, combined cardiac procedures, complications of cardiac surgery, unnecessary delay of abdominal surgery, and abdominal wound complications. Major abdominal wound complications were seen in 38%. Patients undergoing cardiac surgery may develop a variety of common abdominal surgical disorders. Patients so inclined cannot be identified prior to cardiac surgery. Ulcer prophylaxis, wound management, prompt resuscitation, and timely surgery are critical.

From the Department of Surgery, University of South Florida, Tampa, Florida

THE ACUTE SURGICAL ABDOMEN following cardiac surgery and extracorporeal circulation is a serious, though infrequent, development. Over the past 20 years several authors have addressed the subject of *general surgical* complications after open-heart surgery.[1-3] These have been small series generally involving nonoperative complications. Hyperbilirubinemia, pancreatitis, gastrointestinal bleeding, and nonspecific abdominal pain have frequently been noted as the general surgical complications.[1,4,5] Few studies, each involving no more than a handful of patients, have addressed the acute surgical abdomen following cardiac operations involving cardiopulmonary bypass.[6,7]

We undertook this study involving a large number of patients to determine the type and frequency of intra-abdominal catastrophies that occur after cardiac surgery involving extracorporeal circulation. Specifically, we set out to find common factors in patients who develop an acute surgical abdomen after cardiac surgery. Additionally, we sought to characterize a subgroup of patients undergoing cardiac surgery that are prone to develop an acute surgical abdomen to enable us to diagnose the abdominal condition earlier or, ideally, to prevent the acute surgical abdomen from occurring in this setting.

Materials and Methods

Between January 1, 1972 and June 1, 1984, 7140 patients underwent cardiac surgery involving extracorporeal circulation at one university teaching program. These patients form the basis of this retrospective review. Data were obtained from medical records, operative reports, surgical pathology reports, and attending surgeon records.

The hospital course of each patient was reviewed for the following parameters. The patient's health prior to cardiac surgery was evaluated through history and physical examination, routine laboratory testing, and objective tests of cardiac performance (*e.g.*, muga scans). Details concerning the cardiac operation were sought, including the number and type of procedures performed at each cardiac operation, the duration of extracorporeal circulation, and the duration of aortic occlusion. Signs and symptoms of abdominal disease in the period after cardiac surgery were sought. Pertinent laboratory tests and diagnostic studies were reviewed. Details of the abdominal operations were assessed; postoperative notes, pathology reports, and operative reports were reviewed. Intraoperative findings, operative procedures, and postoperative morbidity and mortality rates were reviewed. Patient follow-up continued until patient death or until resolution of the abdominal disorder.

Results

Twenty-one patients (0.29%), 13 males and 8 females, with an average age of 66 years (range: 44–78 yr) developed an acute surgical abdomen after cardiac surgery and extracorporeal circulation. Twenty-three abdominal operations were performed on this group. Eighteen patients developed this complication since January 1980 (Table 1).

Review of the medical histories of the 21 patients was largely unremarkable. One patient had a history of peptic ulcer disease and two had a history of cholelithiasis. Review of the admission physical examinations revealed that one patient had an inguinal hernia at admission. None of the 21 patients had a rectal exam nor had stool tested for occult blood upon admission.

Arterial blood gas analysis was not performed upon five patients prior to cardiac surgery. Two patients had arterial P_{CO_2} greater than 50 torr, and two patients had arterial PO_2 less than 60 torr. Elevated serum creatine levels were noted in eight patients (38%), and elevated serum alkaline phosphate levels were noted in nine patients (43%) at admission. Only one patient had a hematocrit less than 35%. One patient had a minimally elevated bilirubin. The mean ejection fraction for the 21 patients was 62%, with a range of 35–89%.

Ten of the 21 patients (48%) that developed an acute surgical abdomen after cardiac surgery did so after elective aortocoronary bypass grafting (Table 2). One third of the patients underwent elective combined cardiac procedures involving more than one of the following: aortocoronary bypass grafting, cardiac valve replacement, ventricular aneurysmectomy, and atrial septal defect repair (Table 2). One patient underwent a complex *redo valve* replacement in the course of having multiple valves replaced. There were three emergency operations. Patients undergoing combined cardiac procedures prior to developing an acute surgical abdomen had longer *pump times* (mean ± SEM; 131 ± 17 min, 81 ± 5 min; $p < 0.05$) than patients undergoing a single cardiac procedure.

The hospital course following cardiac surgery and preceding the development of an acute surgical abdomen for the 21 patients in this series could easily be divided into two groups. The first group, six patients, had an uneventful course after cardiac surgery before developing an acute surgical abdomen. Of these 6 patients, 3 developed complications of peptic ulcer disease (2 hemorrhage, 1 perforation), 1 developed an intestinal infarction, 1 developed a sigmoid colon perforation, and 1 underwent a nondiagnostic laparotomy. This last patient was later reoperated on and found to have intestinal ischemia with an infarcted perforated cecum. Intestinal ischemia with infarction in this patient was believed to be due to a low flow state, which persisted after the nondiagnostic laparotomy.

Each of the remaining 15 patients experienced a complex course with major complications after cardiac surgery prior to developing an acute surgical abdomen. The three patients who had undergone emergency cardiac operations were in this group. Seven of the 15 patients developed eight complications that were directly attributable to their cardiac surgery; 3 patients developed sternal infections with mediastinitis, 2 patients experienced excessive bleeding that did not require reoperation, and 3 patients experienced excessive bleeding that did require reoperation, 2 because of cardiac tamponade. In each of these seven patients, these complications preceded complications experienced by all 15 patients of this group prior to the onset of an acute surgical abdomen: renal failure, prolonged ileus, respiratory failure, stroke, hemorrhagic shock, cardiogenic shock, and sepsis. In general, the 15 patients who experienced complex courses after cardiac surgery developed acute surgical abdomens due to complications of peptic ulcer disease, deceased intestinal blood flow, and cholecystitis (Table 3).

In the series of 21 patients as a whole, 6 patients developed an acute surgical abdomen because of complications of peptic ulcer disease; 2 died. Five patients developed an acute surgical abdomen because of colonic perforations; 1 died. Four patients developed an acute

surgical abdomen because of intestinal infarction; 2 died. Two patients developed an acute surgical abdomen because of acalculus cholecystitis leading to cholecystectomy and in 2 other patients calculus cholecystitis was concomitantly noted at celiotomy, leading to cholecystostomy (Table 4).

None of the six patients who developed an acute surgical abdomen due to complications of peptic ulcer disease were on antiulcer medication after cardiac surgery. Four of the six patients had a history of ulcer disease, had post pump complications (mediastinitis, excessive bleeding after cardiac surgery), or were taking aspirin. Two of the six patients (33%) died, including one who experienced reperforation of an ulcer.

The underlying cause of the eventual acute surgical abdomen in three patients was noted at the admission medical history or physical examination. One patient with a history of peptic ulcer disease experienced perforation of a peptic ulcer after cardiac surgery leading to an acute surgical abdomen. One patient with a history of cholelithiasis developed cholecystitis and a subsequent *low flow state* leading to an ischemic perforated cecum. Another patient, noted to have an inguinal hernia upon admission physical examination, developed an incarcerated inguinal hernia leading to an acute surgical abdomen in the period following cardiac surgery. Alternatively, 18 patients developed an acute surgical abdomen, which, by the admission history and physical examination alone, was unexpected.

Complications occurred after the abdominal operations. Abdominal wound sepsis was seen in 8 of 21 patients (38%). This is despite death in two patients hours after abdominal surgery. Excluding these two patients, wound sepsis was seen in 8 of 19 patients (42%). In each case wound sepsis prolonged hospitalization. In 3 of these 8 patients (38%) incisional dehiscence developed, and 2 of these 8 patients (25%) died.

Cerebrovascular accidents (5%), obstructive uropathy (5%), congestive heart failure (14%), nutritional depletion (14%), respiratory failure (26%), and sepsis (38%) with multiorgan failure (10%) were noted to develop after the abdominal operations.

The overall mortality rate in this series was 24%. Death was due to multiorgan failure and sepsis in four patients and a massive myocardial infarction in one patient. When the abdominal operation was delayed for more than 24 hours after the recognition of an acute surgical abdomen, the mortality rate was 75% (3 of 4 patients). Emergency cardiac operations, combined cardiac procedures, post pump complications (*e.g.*, cardiac tamponade, bleeding, and mediastinitis), and a complex course after cardiac surgery prior to developing an acute surgical abdomen were all associated with higher mortality rates in patients who developed an acute surgical abdomen after cardiac surgery involving extracorporeal circulation (Table 5).

Discussion

The development of an acute surgical abdomen after cardiac operations involving extracorporeal circulation is an infrequent complication with significant morbidity and mortality rates. Such a development is not a phenomenon unique to the *pioneer* days of cardiac surgery and extracorporeal circulation. In this review, the incidence of the acute surgical abdomen after cardiac operations was nearly four times greater after 1980 than in the years prior to 1980.

Admission histories and physical examinations were neither complete nor exhaustive. Laboratory evaluation, similarly, was generally incomplete. Data available reflect an older population with medical problems, quite consistent with the age, sex, and general fair health of patients undergoing cardiac surgery. The ejection frac-

tions of patients in this study were generally good prior to cardiac surgery.

Preoperative medical histories and physical examinations, laboratory data, and tests of cardiac function as performed were not helpful in predicting the subsequent development of an acute surgical abdomen. There appears to be no common factors among patients who develop an acute surgical abdomen after cardiac surgery. For the purpose of early diagnosis or prevention, we were additionally unable to characterize a subgroup of patients undergoing cardiac surgery who were prone to developing an acute surgical abdomen.

The patients in this review could conveniently be divided into two groups depending upon their course after their cardiac operation. The morbidity and mortality rates of these groups was significantly different. Those six patients with an uneventful course after cardiac surgery prior to the sudden development of an acute surgical abdomen experienced no mortality. The acute surgical abdomen in these patients was generally due to complications of peptic ulcer disease or low intestinal blood flow. The other 15 patients experienced a very complex course after their cardiac operation. All of these patients developed major medical problems such as renal failure, sepsis, hemorrhagic shock, cardiogenic shock, and cerebrovascular accidents prior to the development of their acute surgical abdomen. A subgroup of seven patients had additional problems, including mediastinitis, sternal infections, and excessive post pump bleeding, all attributable to their cardiac operation directly. The mortality rate in this group of 15 patients was very high (33%), in contrast to the patients with an uneventful course after cardiac surgery prior to developing an acute surgical abdomen (0%).

Major medical problems and post pump complications should be sought when patients suspected of having an acute surgical abdomen after cardiac surgery are encountered. These problems and complications are associated with a high mortality rate in this setting. Cardiac operations that are done as emergency procedures, cardiac operations that consist of combined procedures (and prolonged extracorporeal perfusion), and reoperative cardiac operations are cardiac operations that are associated with a poor prognosis in patients who subsequently develop an acute surgical abdomen. Delay in performing abdominal surgery once an acute surgical abdomen is recognized is associated with a prohibitive mortality rate.

There is a plethora of complications that can occur after abdominal surgery. Sepsis is a frequent and grave complication. Wound complications are also frequent. Wound care must be taken very seriously after abdominal surgery in these patients. Incision placement must be well thought out prior to abdominal surgery. Locations for potential stomas should be marked preoperatively to ensure acceptable placement and optimal daily care postoperatively. There should be no pressure to perform primary wound closures; delayed primary closures should be frequently utilized. Wounds that are left open should be aggressively cared for and debrided frequently. In this setting wound dressings should be changed frequently, and evidence of wound sepsis should be continuously sought.

In this review the abdominal causes of the acute surgical abdomens were not unusual abdominal disease processes. These processes are the common general surgical problems that are seen in most every surgical practice. *Fascinomas* were not encountered. In general, the abdominal disorders that resulted in the development of the acute surgical abdomen were due to altered intestinal blood flow, peptic ulcer disease, cholecystitis, and intestinal perforation.

Patients with an ulcer history, patients who have a particularly stressful course after cardiac surgery, and patients who require aspirin treatment after cardiac surgery should have antiulcer medications routinely after cardiac surgery.

When caring for patients suspected of having an acute surgical abdomen after cardiac surgery, several factors must be kept in mind. Patients must undergo an aggressive, though directed, workup to diagnose the abdominal process causing the suspected acute surgical abdomen. Surgery must be performed promptly when indicated. Abdominal surgery should be delayed only for prompt and aggressive resuscitation; unnecessary delay is accompanied by unacceptable mortality rates. It is not acceptable to deem patients *too sick to operate on* since patients after cardiac revascularization are more suitable for abdominal surgery than prior to their cardiac surgery.[8] Furthermore, patients in this setting are not likely to become more suitable candidates for surgery with the unnecessary passage of time. Arteriograms and other invasive diagnostic studies should not be used unless therapeutic decisions will be based on their results.

Gastric Mucosal Blood Flow in Misoprostol Pretreated Aspirin-induced Ulceration

THEOPHILUS J. GANA, M.D., BRIAN R. MACPHERSON, PH.D., and JARLEY KOO, M.D. M.SC.

To determine whether topical misoprostol (a synthetic PGE$_1$ analog) pretreatment will increase or prevent a decrease in gastric mucosal blood flow (GMBF) during topical aspirin administration, we studied focal GMBF simultaneously by hydrogen gas clearance in a split canine gastric chamber model with one side as control. In the test chamber, immediately after topical misoprostol, there was a transient and significant increase (18%) in GMBF (55.71 ± 7.80 to 65.84 ± 6.12 mL/min/100 g; $p < 0.05$). After 15 minutes, GMBF returned to premisoprostol levels and then showed a graded drop throughout the aspirin and postaspirin periods. No grossly visible mucosal lesions were observed. In the control chamber, mucosal lesions were observed 45 minutes after aspirin administration accompanied by a graded drop in GMBF throughout the experiments. Misoprostol neither produced a sustained increase in GMBF nor prevented the subsequent reduction in GMBF induced by aspirin. Therefore, maintenance of GMBF may not be important in cytoprotection by misoprostol. The sustained nonparietal secretion induced by this synthetic PGE$_1$ analog may be important in gastric cytoprotection.

THE PRECISE MECHANISM(S) of gastric cytoprotection by prostaglandins (PG) is not known. The circulatory hypothesis proposes that the cytoprotective action is mediated through an increase in gastric mucosal blood flow (GMBF).[1-7] This hypothesis has, however, been faced with problems including (1) the results of studies of the effects of PG on GMBF have been inconsistent[3]; (2) though a number of the A, E, and I PG increase GMBF,[3,8-10] PGF$_{2\alpha}$, also cytoprotective,[11,12] is a known vasoconstrictor[8,13-16]; and (3) 16,16-dimethyl PGE$_2$ has been reported to prevent ulcer formation in the absence of arterial perfusion in isolated canine gastric mucosa,[17] in amphibian gastric mucosa *in vitro,*[18] and in gastric cell cultures in rats.[19,20]

From the Surgical-Medical Research Institute and the Departments of Surgery and Anatomy and Cell Biology, the University of Alberta, Edmonton, Alberta, Canada

Misoprostol is a synthetic PGE$_1$ analog that has been reported to have both gastric antisecretory and cytoprotective properties.[21-30] There have been few reports in the literature on the effects of misoprostol on gastric blood flow. While some investigators have reported an increase in total gastric blood flow[2] and gastric mucosal blood volume,[31] others have reported either a decrease in total GMBF[23] or no effect.[27] We designed this study to elucidate further the circulatory hypothesis by a controlled investigation of focal GMBF changes using the hydrogen gas clearance (HGC) technique before, during, and after misoprostol pretreatment of aspirin-induced mucosal injury in a canine chambered gastric segment model. Specifically, the aim of this study was to test the hypothesis that pretreatment of the gastric mucosa with an antisecretory dose of misoprostol would increase or maintain gastric mucosal blood flow during aspirin injury. Second, the fluid and ionic fluxes were measured to determine any interrelationship between GMBF, fluid/ionic fluxes, and gastric cytoprotection.

Materials and Methods

Surgical Preparation

Four adult mongrel dogs of either sex, weighing 20–30 kg, were anesthetized with sodium pentobarbital (25 mg/kg) after a 24-hour fast (only water *ad libitum*). The dogs were intubated and maintained on a Harvard respirator (Harvard Apparatus, South Natick, MA) throughout each experiment. A hind leg vein was cannulated with a polyethylene catheter (PE 200) for infusion of 0.9% sodium chloride for the maintenance of hydration and a stable blood pressure. Arterial blood pressure was directly monitored by a saline-filled polyethylene cath-

Submitted for publication: September 14, 1987.

eter (PE 200) in the left femoral artery via a Statham Gould P 23 Db transducer (Gould Statham Instruments Inc., Hato Ray, Puerto Rico). Following a midline laparotomy and splenectomy, a split chambered segment model of the gastric corpus with an isolated vascular pedicle was prepared according to the method of Moody and Durbin.[32] This model permits the use of one side of the chamber as test, the other as control and provides gastric mucosal surface of 17 cm^2 in each side. We have shown that electrode-mucosa contact is not a problem in this experimental model.[33] Body temperature and the temperature of the preparation were maintained by an electric blanket and infrared lamps. The preparation was allowed to stabilize for 60 minutes after surgery.

Experimental Design

Focal GMBF measurements were performed once every 15-minutes by two HGC electrodes placed in contact with the mucosa in each lumen of the chamber. One electrode was located in the upper and the other in the lower quadrants of each lumen throughout the experiments. Once the electrodes had been located at the beginning of each experiment there was no relocation throughout the experiments. Bathing solutions (8 mL) were instilled into and recovered from each lumen every 15-minutes as follows:

Test chamber. (1) basal periods (60 min): 100 mmol/L HCl + 50 mmol/L NaCl; (2) misoprostol periods (30 min): 100 mmol/L HCl + 50 mmol/L NaCl + 1 mL misoprostol (200 μg); (3) aspirin periods (60 min): 100 mmol/L HCl + 50 mmol/L NaCl + 20 mmol/L aspirin; and (4) postaspirin periods (120 min): same as for the basal periods.

Control chamber. Solutions instilled were the same as for the test chamber except in (2) where instead of misoprostol, 1 mL of vehicle (0.2 mL absolute ethanol + 0.8 mL phosphate buffer) was added to HCl and NaCl. Laboratory assays were performed on the recovered bathing solutions to determine the changes in volume, pH, sodium, and hydrogen ion concentrations. The pH of the bathing solutions and hydrogen ion concentration (titratable acid) were measured using a pH meter (Radiometer Copenhagen, Bach-Simpson Ltd., London, Ontario, Canada). Titration of the recovered solutions were performed to pH 2, the pH of the instilled solutions, with 0.1 N NaOH. Sodium ion concentration was measured with a Nova 1 Na^+/K^+ analyzer (Nova Biomedical, Newton, MA). The difference between the product of concentration and volume for the instilled and recovered solutions per 15 minute periods are the net fluxes expressed for sodium and hydrogen ions in the results below.

Misoprostol Preparation

Misoprostol was received as neat chemical in dry ice (G.D. Searle and Co. Inc., Skokie, IL). It was dissolved in isotonic 20% ethanol-containing phosphate buffer (pH 7.4). The misoprostol stock-solution was stored in vials at below −20 C when not in use and allowed to thaw to room temperature before use.

Hydrogen Gas Clearance

This was performed by standard technique as described previously.[33,34] The four HGC electrodes (Unique Medical Co. Ltd., Tokyo) with the four reference Ag/AgCl skin electrodes (Red Dot, 3M Canada Inc., London, Ontario, Canada) were connected to a Beckman multichannel recorder (Beckman Type R Dynograph, Beckman Instruments Inc., Schiller Park, IL) to obtain a permanent record of the measurements.

Histology

Following the termination of each experiment the mucosa and submucosa of tissue from both chambers were quickly dissected from the underlying muscularis and immersed in 10% neutral buffered formalin. The mucosa-submucosa preparation was then spread out and pinned flat on a cork slab within the fixative. After 24 hours fixation the tissue was Swiss-rolled and stored in 70% ethanol. Three random slices from each roll were resected and processed through to either paraffin and stained with hematoxylin and eosin or embedded in glycol methacrylate and stained with methylene blue-basic fuchsin. The slides were coded and examined blindly. Several morphologic parameters were noted and/or recorded for each sample including mucosal height, number and spatial relationship of gastric glands, integrity and continuity of the epithelial sheet, and presence of inflammatory cells in the lamina propria, as well as the appearance of mucosal capillaries. The sections were organized into groups based on the morphologic analysis before the code was broken. Comparison of the groupings permitted evaluation of consistent morphologic features within and between each group.

Data Analysis

All data are expressed as mean ± SE. GMBF data are expressed in mL/min/100 g of tissue. Statistical analysis for significance at the 5% level was performed using either the paired Student's t test or ANOVA, and linear regression analysis. Because there is a significant difference in GMBF between the upper and lower quadrants of the gastric chamber model, in comparing flow values between the test and control chambers, they were paired upper *versus* upper and lower *versus* lower in the t-tests.

Results

Gross and Microscopic Appearance

In the test chamber, there was gross mucosal swelling within 5 minutes of topical application of 200 μg of misoprostol, a feature that persisted throughout the experimental period. No grossly visible lesions were observed either during or after aspirin administration. Mucosal integrity was maintained throughout the experiment except for an obvious increase in the amount of mucus adherent to the luminal surface. Histologic evaluation of the misoprostol-treated tissue revealed a swollen lamina propria giving the gastric glands a widely spaced appearance and increased mucosal height. There was no increase in cellularity of the mucosa. Vascular channels were easily identifiable, dilated but empty of any cellular components (Fig. 1).

In the control chamber, multiple focal punctate lesions appeared on the mucosa 45 minutes after aspirin administration. Mucosal swelling did not occur within this chamber. Typical aspirin-induced superficial erosions could be identified in localized areas (Fig. 2). Although the majority of the tissue exhibited a normal morphology, there was frequent observation of a widened zone of lamina propria just beneath the surface epithelium (Fig. 3).

Gastric Mucosal Blood Flow

Resting focal GMBF measured by the four HGC electrodes consecutively for 1 hour revealed a positional effect on blood flow in the four quadrants of the double-lumen chamber. In both test and control chambers, there was a highly significant difference between the

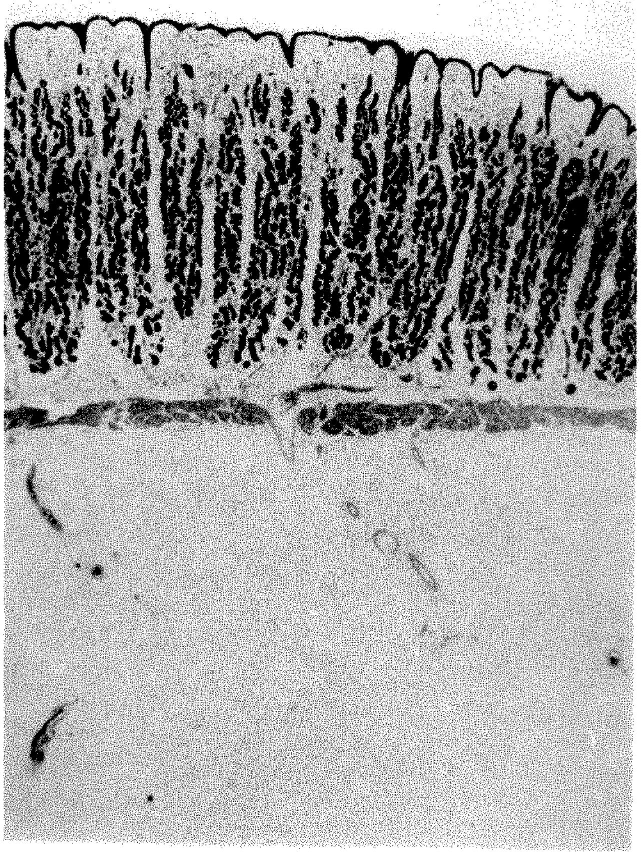

FIG. 1. Tissue from the test chamber illustrating the swollen, edematous appearance of the mucosa following misoprostol administration. The submucosa exhibits a similar reaction. Note the increased height of the mucosa when compared to Figure 2 (methacrylate, MBBF stain, original magnification ×100).

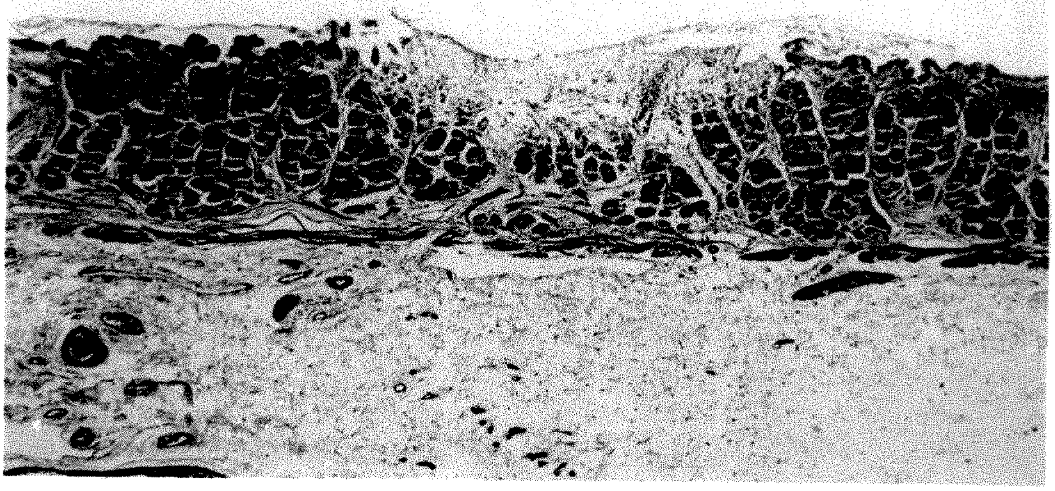
FIG. 2. A section through an aspirin-induced lesion in tissue from the control chamber. Areas adjacent to the lesion as well as the submucosa exhibit otherwise normal morphology (paraffin, hematoxylin and eosin, original magnification ×100).



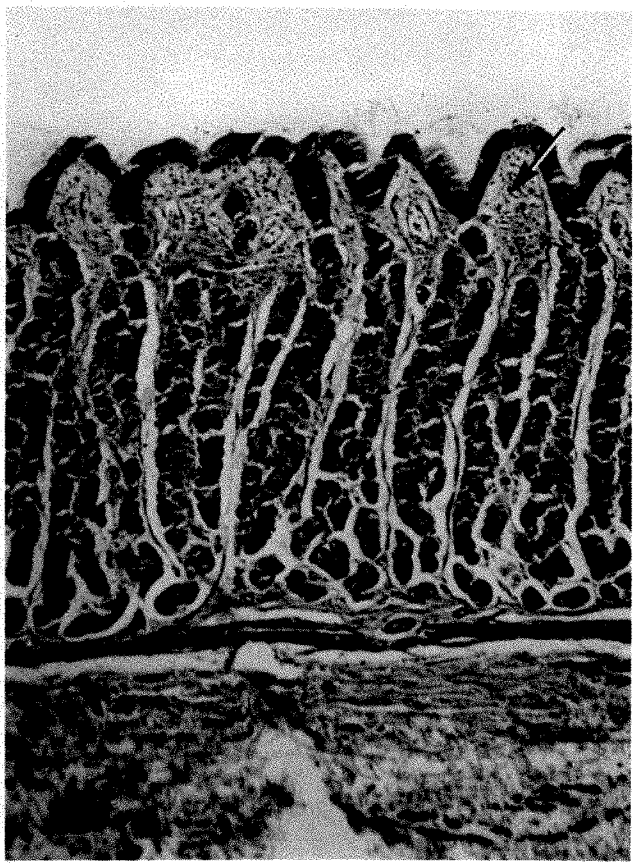


FIG. 3. Histologic appearance of the majority of tissue from the control chamber. Note the widened zone of lamina propria immediately beneath the surface epithelium (arrow) (paraffin, hematoxylin and eosin, original magnification ×160).

mean (± SE) resting GMBF values in the two upper and lower quadrants. Between the two chambers, there were no significant differences in the mean resting GMBF values recorded in the upper and lower quadrants (upper test: 66.31 ± 6.86; upper control: 63.66 ± 6.52; $p > 0.05$; lower test: 48.97 ± 4.08; lower control: 41.67 ± 3.45; $p > 0.05$; t-test). Linear regression analysis revealed a highly significant correlation between consecutive resting GMBF values recorded by the upper and lower electrodes located within each chamber (test: $r = 0.7511, N = 13, p < 0.01$; control: $r = 0.7151, N = 13, p < 0.01$), but consecutive resting GMBF values recorded by electrodes located on the same horizontal axis in the two chambers were not correlated.

Figure 4 depicts the simultaneous sequential changes in mean (±SE) GMBF values measured in the test and control chambers during the basal, misoprostol/control, aspirin, and postaspirin periods. In both chambers, the four consecutive mean GMBF values obtained in the basal periods were not significantly different from each other (test: 64.36 ± 10.77, 66.70 ± 9.36, 54.82 ± 7.54, and 55.71 ± 7.80; $p > 0.05$; control: 56.09 ± 6.23, 55.79 ± 7.99, 52.77 ± 9.53, and 48.37 ± 7.58; $p > 0.05$; ANOVA). In the test chamber immediately after the administration of misoprostol, there was a significant and transient increase (18%) in GMBF in the first misoprostol period above the final basal period mean flow value (from 55.71 ± 7.80 to 65.84 ± 6.12; $p < 0.05$; t-test). In the second misoprostol period, the mean GMBF value of 51.27 ± 6.10 was not significantly different from the final basal period mean flow value, indicating a return of GMBF to premisoprostol (basal) levels within 15 minutes even though administration of misoprostol was continued for an additional 15 minutes. After the misoprostol periods focal GMBF in the test chamber showed a graded drop throughout the aspirin periods, became significantly less than the final basal period mean flow value in the second aspirin period, and remained so until the end of the experiments. In the control chamber, there was a graded drop in GMBF throughout the aspirin periods, which became significantly different from the final basal period during the first postaspirin period and remained stable but significantly less than the basal period mean flow value in the remaining periods of the experiments.

Comparison of the simultaneous GMBF values obtained from the two chambers revealed no significant differences except during the first misoprostol/control period (test: 65.84 ± 6.12; control 41.43 ± 6.25; $p < 0.01$; t-test). In the second misoprostol/control period, though the mean GMBF value in the test chamber remained higher than in the control chamber, the difference was not significant statistically. Thereafter with aspirin, GMBF dropped in both chambers and re-

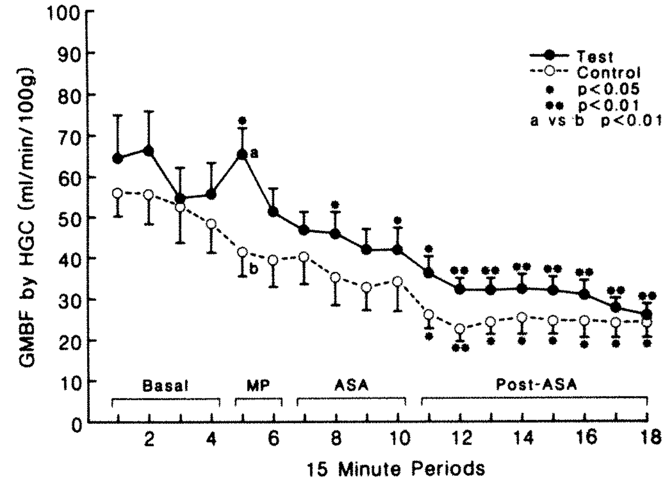

FIG. 4. The simultaneous sequential changes in mean (± SE) GMBF measured in the test and control chambers during the basal, misoprostol/control, aspirin and postaspirin periods. N = 8 for each point. Asterisks indicate significant differences from the final basal period mean (±SE) flow value within each chamber. MP = misoprostol/control periods; ASA = aspirin periods; HGC = hydrogen gas clearance.

TABLE 1. *Net Ionic and Fluid Fluxes in the Test and Control Gastric Chambers*

Periods	Flux Types	Test Chamber	Control Chamber	Test *Versus* Control P Value
Basal	Fluid (mL/15 min)	+0.02 ± 0.15	+0.09 ± 0.18	NS
	Na^+ (μmoL/15 min)	+79.91 ± 25.29	+95.63 ± 29.35	NS
	H^+ (μmoL/15 min)	−64.83 ± 15.69	−69.27 ± 17.38	NS
Misoprostol/control	Fluid (mL/15 min)	+3.36 ± 0.78*	+0.18 ± 0.28	<0.01
	Na^+ (μmoL/15 min)	+593.45 ± 103.21*	+171.42 ± 17.94	<0.01
	H^+ (μmoL/15 min)	−101.27 ± 27.65	−133.51 ± 35.99	NS
Aspirin	Fluid (mL/15 min)	+1.06 ± 0.29†	−0.49 ± 0.22	<0.01
	Na^+ (μmoL/15 min)	+213.52 ± 35.63†	−4.06 ± 11.11†	<0.001
	H^+ (μmoL/15 min)	+5.52 ± 12.02†	−20.53 ± 29.33	NS
Postaspirin	Fluid (mL/15 min)	+0.17 ± 0.07	−0.48 ± 0.11†	<0.001
	Na^+ (μmoL/15 min)	+84.28 ± 10.97	+26.52 ± 8.02†	<0.01
	H^+ (μmoL/15 min)	−45.49 ± 5.63	−88.30 ± 13.90	<0.01

Values are given as mean ± SE. Plus (+) sign denotes a net luminal gain or efflux and a minus (−) sign a net luminal loss or influx.

* Significant difference from the basal period within the same chamber, $p < 0.001$.

† Significant difference from the basal period within the same chamber, $p < 0.01$.

NS = not significant.

mained higher though insignificantly so in the test chamber.

Ionic Fluxes

The results of the net fluxes of ions and fluid are summarized in Table 1. In this text influx denoted by a minus sign in front of the flux value means net luminal loss while efflux denoted by a plus sign means net luminal gain.

Sodium ion flux. In the test chamber immediately after misoprostol administration, there was a highly significant increase in Na^+ efflux into the lumen that was sustained until the end of the aspirin periods. Na^+ efflux returned to basal levels during the postaspirin periods (Fig. 5). In the control chamber during aspirin administration, there was a significant Na^+ influx from the lumen. This was reversed in the postaspirin periods, but the Na^+ efflux remained significantly less than that of the basal period.

Fluid flux across the mucosa behaved in exactly the same way as sodium in the test chamber (Fig. 6). In the control chamber, there was an insignificant fluid influx after the control period.

There were highly significant linear correlations between net changes in Na^+ and fluid in the test ($r = 0.9903$, $N = 18$, $p < 0.001$) and control ($r = 0.8652$, $N = 18$, $p < 0.001$) chambers.

Hydrogen ion flux. In the test chamber there was a significant ($p < 0.01$, t-test) H^+ efflux in the aspirin periods. In the control chamber there was no significant change in the net H^+ flux throughout the experiments. The only difference between the test and control

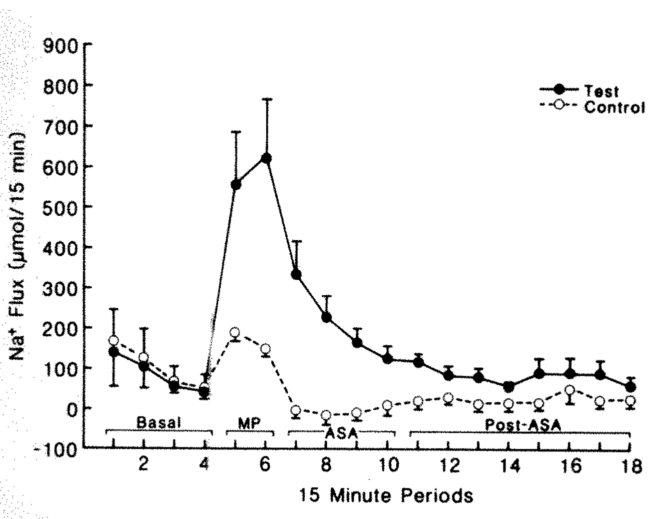

FIG. 5. The sequential changes in the flux of sodium in the test and control chambers during the basal, misoprostol/control, aspirin, and postaspirin periods.

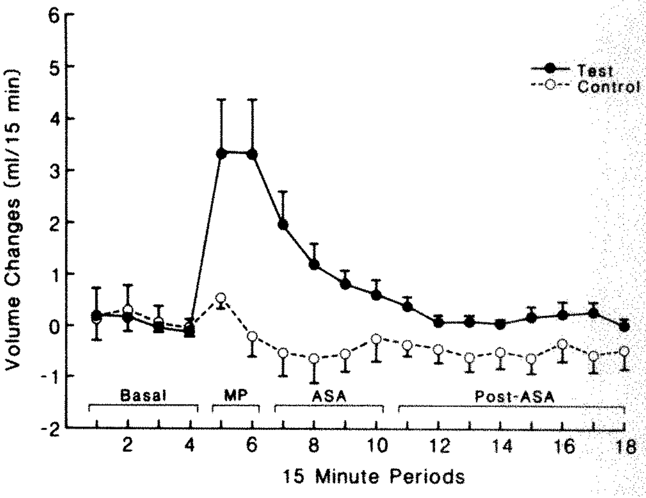

FIG. 6. The sequential changes in the flux of fluid in the test and control chambers during the basal, misoprostol/control, aspirin, and postaspirin periods. The pattern of the changes are identical to that of sodium.

chambers was a significantly higher H^+ influx in the latter in the postaspirin periods.

Relationship Between Gastric Mucosal Blood Flow and Fluxes

In the test chamber no correlations were observed between GMBF and the fluxes of Na^+, H^+, and fluid. In the control chamber, there were highly significant linear correlations between GMBF and fluid flux ($r = 0.7364$, $N = 18$, $p < 0.001$), and GMBF and Na^+ flux ($r = 0.5928$, $N = 18$, $p < 0.01$).

Discussion

Though the precise mechanism(s) of gastric cytoprotection is not known, some experimental evidence has emerged in support of the circulatory hypothesis.[1-6] According to the latter, an increase in GMBF is believed to (1) maintain an adequate supply of oxygen and nutrients to the mucosal cells, thereby preventing a deficit in energy metabolism; (2) supply bicarbonate that will buffer back-diffused hydrogen ions, and (3) rapidly eliminate both back-diffused hydrogen ions and the damaging agent that may have gained access into the subepithelial tissues.[35,36] Discrepancies in the results of previous studies on the role of GMBF in cytoprotection may be due to measurement techniques employed, experimental models, experimental designs, and route of administration of the PG.

HGC is a noninvasive method that has been validated for focal GMBF measurements in animals[37-39] and man.[37] Using this technique in our study after topical administration of misoprostol, we observed an immediate and small transient increase (18%) in focal GMBF. The nature of this increase in blood flow is suggestive of a direct vasodilatory effect by misoprostol. The results of this study differ from that of Leung et al.[27] who also (using HGC) reported no effect by misoprostol on resting GMBF and on GMBF during inhibition of stimulated acid secretion in rats. The differences may be due to the fact that in their study GMBF measurements were commenced 15 minutes after misoprostol treatment. Similar to our results, Sato et al.[31] reported that misoprostol increased gastric mucosal blood volume by 10–25% at various sites in the fundus and antrum as measured by reflectance spectrophotometry in healthy human male volunteers. Likewise, Larsen et al.[2] observed an increase in total gastric blood flow obtained by venous outflow in the canine chambered gastric segment model after topical misoprostol. Colton et al.[23] observed that misoprostol at doses that inhibited histamine-stimulated acid secretion reduced GMBF as measured by aminopyrine clearance, but the ratio (R) of GMBF to rate of acid secretion was actually increased. This indicated that misoprostol has a vasodilating effect in the gastric mucosal vascular bed. Similarly, intra-arterial PGE_1 has been reported to increase significantly total (by venous outflow and radioactive microspheres) and mucosal blood flow (by radioactive microspheres) in canine chambered gastric segment model.[40] Also, topical PGE_1 has been shown to dose-dependently increase superficial gastric mucosal microvascular flow measured by *in vivo* microscopy in rats.[41] The findings in this study confirm these earlier observations that misoprostol, a synthetic PGE_1 analog, is a vasodilator in the gastric mucosal vascular bed.

Our results also confirmed previous reports that misoprostol is cytoprotective.[2,24-26,28-30] The degree of mucosal swelling observed after misoprostol administration was surprising. The histology clearly attributed this gross observation to an edematous reaction within the lamina propria causing increased spacing and separation of the gastric glands. A thick mucoid layer overlying the surface epithelium was also evident in these sections. The aspirin-induced lesions were similar in severity and morphology to those described by other authors.[42] The frequent observation of a widened zone of lamina propria immediately below the surface epithelium is reminiscent of the fashion in which this layer is shed in response to necrotizing agents such as absolute ethanol.[43] The fact that many regions of tissue from the control chambers lacked any evidence of mucosal disruption could be attributed to the random nature of sample site selection as well as the length of the experimental period. It has been shown that epithelial repair under these conditions can begin within 3, and is completed within 60, minutes.[44]

The extent to which GMBF contributes to cytoprotection is unknown. Larsen et al, in the aforementioned study observed an increase in total gastric blood flow by misoprostol of over 400% that was sustained during subsequent aspirin-shock injury, and concluded that the increase in blood flow was responsible for the cytoprotective effects.[2] Recently, we have shown that topical aspirin induces a reduction in GMBF of varying degrees and that mucosal areas with blood flow reduced to below a *critical value* develop gross damage.[34] In this study we were unable to demonstrate that misoprostol pretreatment reverses aspirin-induced decrease in GMBF or maintains blood flow after aspirin administration. Our results therefore do not suggest that this transient vasoactive effect is an important mechanism of gastric cytoprotection.

In terms of ionic fluxes, Colton et al.[24] found no significant difference in the influx of H^+ and Cl^-, and efflux of Na^+ observed with misoprostol and aspirin when administered into canine Heidenhain pouches separately or together. They concluded that influx of H^+ and efflux of Na^+ from the stomach does not necessarily indicate mucosal damage. On the contrary, Larsen et al.[2] have reported that misoprostol had a negligible effect on the fluxes of Na^+, Cl^-, and H^+ that were not significantly different from the controls. In this study the only consistent flux changes observed were the significant increase in the efflux of Na^+ and fluid into the test chamber lumen immediately after administration of misoprostol. The efflux of Na^+ and fluid could be due to either damage to the gastric mucosal barrier by misoprostol, as was initially attributed to 16,16-dimethyl PGE_2,[45-47] or stimulation of a nonparietal cell secretion rich in Na^+.[48,49] Since no reports have shown that misoprostol damages the mucosa grossly or histologically, and the 200-μg dose of misoprostol used in this study has been experimentally and clinically shown to be cytoprotective, we favor the latter explanation for the observed increase in Na^+ and fluid efflux. The highly significant linear correlation observed in the test chamber between the fluxes of Na^+ and fluid further suggests that these fluxes may be mediated through the same pathway, namely, stimulation of nonparietal secretion rich in Na^+.

We cannot offer any explanation for the findings in H^+ fluxes. It is noteworthy that in the presence of PG, agents that stimulate active secretion of bicarbonate or Na^+-rich fluids,[50,51] disruption of the gastric mucosal barrier by topical damaging agents (*e.g.*, aspirin, alcohol, and bile salts) will not result in the classical picture proposed by Davenport, namely, back diffusion of H^+ and efflux of Na^+ into the lumen.[52] Neutralization of acid by bicarbonate and the large amounts of Na^+ effluxed into the lumen under these circumstances will inevitably alter the net ionic fluxes. This may be the reason for the failure to obtain results consistent with Davenport's hypothesis in this and other studies when an agent that stimulates active secretion of Na^+ bicarbonate is used. This finding also raises questions about the validity of using the efflux of Na^+ and the luminal loss of H^+ as indicators of gastric mucosal barrier damage under these circumstances. The linear relationship between GMBF and the fluxes of Na^+ and fluid in the control but not the test chamber may be accounted for by misoprostol since it is the only different variable between the two chambers.

In conclusion, though our results did show a significant and transient increase in GMBF by misoprostol pretreatment, it did not prevent subsequent decrease in GMBF by aspirin. The sustained efflux of Na^+-rich fluids (*i.e.*, nonparietal cell secretion) induced by this synthetic PGE_1 analog may be important in gastric cytoprotection. Our results confirm that misoprostol is vasodilatory and cytoprotective, and it stimulates nonparietal cell secretion. Further studies of the vasoactive effects of PG as an important mechanism of cytoprotection are required.

Management of Stab Wounds to the Thoracoabdominal Region

A Clinical Approach

JAMES G. MARIADASON, M.D., F.R.C.S., M. H. PARSA, M.D., F.A.C.S., ADOLFO AYUYAO, M.D., F.A.C.S., and HAROLD P. FREEMAN, M.D., F.A.C.S.

We studied 324 patients admitted to Harlem Hospital Center from July 1981 to June 1986 with stab wounds of the thoracoabdominal region (area limited by a coronal circle through the fifth interspaces anteriorly and seventh interspaces posteriorly from above to a subcostal circle 5 cm caudad to the costal margins and 12th ribs from below). We divided this region into 12 zones (six symmetrical zones on each side) using the above upper and lower limits and the costal margins, the midlines, and the anterior and posterior axillary lines. This study was conducted to determine the incidence of transdiaphragmatic penetration for the thoracoabdominal region stab wounds in each of the 12 zones identified for the first time and applied in this study, and the reliability and safety of surgical management based mainly on physical examination. The highest incidence of transdiaphragmatic penetration occurred in stab wounds of the left anterior lower thoracic zone (21.7%). The lowest incidence was 0% and the overall incidence was 11%. Physical examination was accurate in making the diagnosis in 95.4% of all cases and no mortality was associated with a delay in diagnosis that may have resulted from the serial physical examinations. We conclude that this method of selective operative management based on physical examinations is accurate and safe.

From the Trauma Center, Department of Surgery, Harlem Hospital Center, Columbia University College of Physicians and Surgeons, New York, New York

STAB WOUNDS of the chest can penetrate the abdomen across the diaphragm, and stab wounds of the abdomen can penetrate the chest. This propensity for thoracoabdominal or abdominothoracic penetration is mainly confined to an area we consider the thoracoabdominal region. This region is limited cephalad and caudad by a coronal circle running horizontally through the fifth interspaces anteriorly and the seventh interspaces posteriorly; the region is limited by another circle drawn 5 cm below and parallel to the costal margins and 12th ribs.

Management of many of the stab wounds of this region remains controversial, and mandatory laparotomy continues to be advocated by some.[1] The main reason for this controversy is the paucity of information on the true incidence of transdiaphragmatic penetration in wounds of this region and skepticism about the reliability of physical examination in diagnosing such injuries.

The purpose of this study was twofold: (1) to determine the incidence of transdiaphragmatic penetration (thoracoabdominal or abdominothoracic) for stab wounds of each of the 12 subdivisions of the thoracoabdominal region and if the incidence was high enough to justify mandatory laparotomy for any of the subdivisions; (2) to evaluate the accuracy of physical examination and the safety of selective operative management based on serial physical examinations.

Materials and Methods

We studied prospectively 324 patients with stab wounds of the thoracoabdominal region managed between July 1981 and June 1986.

There were 306 males and 18 females (M:F ratio: 11.5:1). The age ranged from 13 to 67, with an average of 31 years.

We divided the thoracoabdominal region into 12 zones using the costal margins, a circle drawn 5 cm caudad and parallel to the costal margins and 12th ribs, a coronal circle cephalad going across the fifth interspaces anteriorly and seventh interspaces posteriorly, the midlines, and the anterior and posterior axillary lines. The zones are anterior, lateral, and posterior lower thoracic and anterior, lateral and posterior subcostal on the right and the left (Figs. 1A and 1B).

All cases were examined to identify the exact location of the external wounds and analyzed based on the following objectives: (1) the incidence of thoracoabdomi-

Note: the lower number of stab wounds and incidence of transdiaphragmatic penetration in the subcostal region compared to that of the lower thoracic; and the higher number of stab wounds of the left than that of the right side.

nal or abdominothoracic penetration (we use the term transdiaphragmatic penetration for both) for each of the 12 zones described; and (2) the degree of reliability of serial physical examinations and the safety of management assessed by the low negative laparotomy rate, and the low mortality and morbidity rates associated with operative surgical intervention made mainly by clinical evaluation.

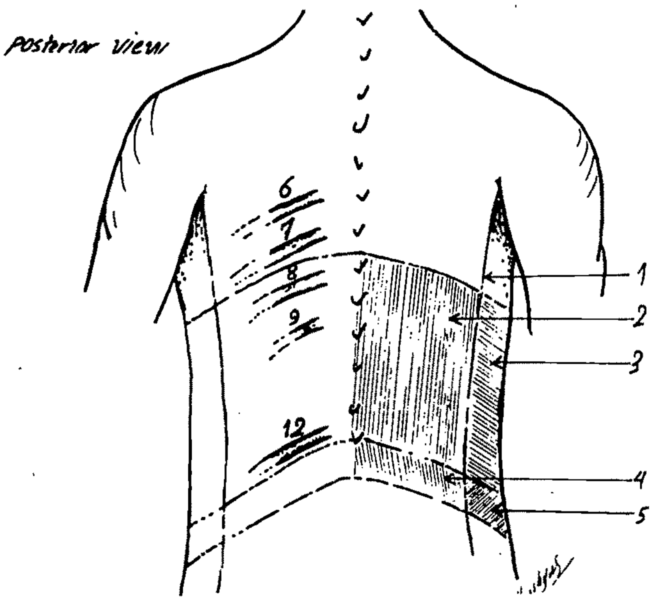

FIG. 1B. Landmarks, lines of division and zones of the thoracoabdominal region posterior view: 1. posterior axillary line, 2. posterior lower thoracic zone, 3. lateral lower thoracic zone, 4. posterior subcostal zone, and 5. lateral subcostal zone. Ribs 6–12 are outlined on the left.

Results

Thirty-six of the 56 patients managed by exploratory laparotomy among 324 patients admitted during the study period had transdiaphragmatic penetration (Table 1). Stab wounds of the left anterior lower thoracic zone were associated with the highest incidence of such transdiaphragmatic penetration (21.7%).

Analysis of the modes of diagnosis in the 36 patients with transdiaphragmatic penetration showed that in 26 cases, clinical findings alone were the main indication for the laparotomy at which diaphragmatic penetration was either confirmed (21 cases) or identified (five cases) (Table 2). One patient underwent emergency thoracotomy for hemorrhagic shock precluding clinical assessment of the abdomen for thoracoabdominal penetration. Nine patients (three with normal abdominal findings and six equivocal) were diagnosed with the aid of

TABLE 3. *Incidence of Negative Laparotomy among 56 Patients Managed by Laparotomy from 324 Patients with Stab Wounds in the Thoracoabdominal Region*

	Laparotomies	All Patients
Stab wounds of the subcostal area	2/25	2/107
%	8	1.87
Stab wounds of the lower chest	3/31	3/217
%	9.6	1.54
All stab wounds of the thoracoabdominal region	5/56	5/324
%	8.9	1.85

plain x-ray films, IVP, ultrasonography, and peritoneal tap/lavage.

Table 3 shows the incidence of negative laparotomy among the 56 patients who underwent exploratory laparotomy. Twenty-five had subcostal wounds and eight of them had diaphragmatic injuries. Of the 25 patients, 23 had significant intra-abdominal injuries. Thirty-one patients had stab wounds of the lower chest. Two among the patients with subcostal wounds and three among the patients with lower thoracic wounds had negative laparotomies. The remaining 268 patients were managed nonoperatively.

In 15 patients with lower thoracic stab wounds, including one with transdiaphragmatic penetration, clinical evaluation of the abdomen was precluded by the need for emergency thoracotomy. Excluding these patients from the 324 leaves 309 patients evaluated by serial physical examinations. Accurate clinical evaluation was achieved in 295 of the 309 (95.5%) [193 of 202 with lower thoracic wounds (95.5%) and 102 of 107 with subcostal wounds (95.3%)]. Six patients had equivocal findings on abdominal examination, which prompted ancillary investigative measures (tap/lavage in four and IVP in two). Physical examination was falsely negative in three patients with transdiaphragmatic penetration

15	38	M	Superior vena caval thrombosis (secondary to subclavian cannulation)	Thoracic	Liver, spleen, and diaphragm	None

(Table 2). In five patients physical examinations were falsely positive resulting in negative laparotomies (Table 3).

Mortalities among the 324 patients admitted with stab wounds of the thoracoabdominal region are listed in Table 4. There were 11 deaths with an overall mortality rate of 3.4%. Four cases were classified as dead on arrival, after emergency thoracotomy was performed for open chest cardiac compression and resuscitation efforts based on possible signs of life. Excluding the four cases of dead on arrival, the mortality rate would be 2.2%. Five were in profound shock upon arrival to the emergency room from exsanguinating cardiac or major vascular injuries. One died of cerebral ischemia resulting from a concomitant carotid artery injury, and one died of sepsis, both 2 weeks after operation. The average age for the mortality group was 43.36 years. Delay in diagnosis was not associated with mortality in any instance.

Table 5 shows the morbidity rate for this series. There were 15 complications in 14 patients. Delay in diagnosis was associated with morbidity in one case; this was a patient with an epigastric stab wound who was observed for 4 days and then discharged asymptomatic only to return 5 weeks later with partial herniation of the stomach into the chest. Following transthoracic repair of his diaphragm he developed a lung abscess. Delay in making the diagnosis up to 18 hours from the time of injury occurred in four other patients, but it was not associated with morbidity.

There were six cases of visceral herniation through the diaphragm to outside. The herniating viscera were stomach in two cases and omentum in the other four.

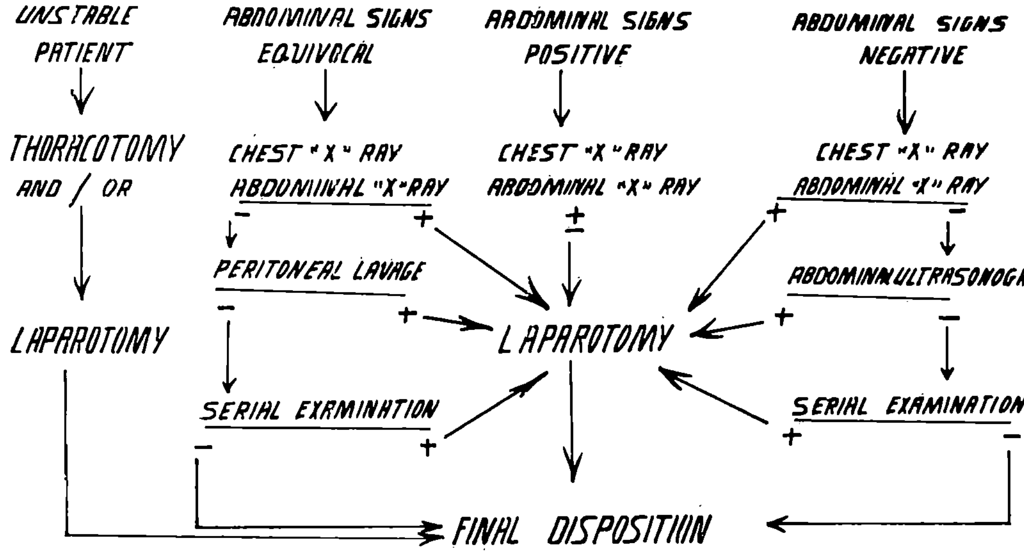

FIG. 2. Our algorithm for management of patients with stab wounds of the thoracoabdominal region.

There were 16 hepatic, 8 splenic, 5 gastric, 4 colonic, 4 renal, and 2 major vascular associated injuries in the 36 cases with transdiaphragmatic penetration. In seven cases diaphragmatic injury was the only visceral injury.

Discussion

In stab wounds of the thoracoabdominal region, mortality and morbidity rates are mainly dependent on concomitant injuries to thoracic and abdominal organs sustained directly or transdiaphragmatically. The diaphragmatic injury per se is not a major factor in development of complications early on, but it can cause delayed morbidity and even mortality.

Optimal and timely management should prevent avoidable mortality and morbidity without excessive use of costly and risk-laden, diagnostic procedures. Mandatory laparotomy for all penetrating wounds of the abdomen and lower chest has been advocated on the grounds that it is the only sure way of making an early diagnosis of transdiaphragmatic penetration.[1–3] But in the only report we could find addressing the incidence of transdiaphragmatic penetration for lower thoracic stab wounds, Moore et al.[4] have indicated an incidence of 15%. Obviously with this incidence mandatory laparotomy would result in a large number of unnecessary operations. Even among patients subjected to laparotomy, missed diaphragm injuries have been reported.[1,5,6] Furthermore, negative laparotomy is not an innocuous procedure with reported mortality rates ranging from 0–6.3%[7–9] and morbidity rates of 17–19%.[9,10] Therefore, mandatory laparotomy is not a satisfactory method of management.

Since Shaftan's report[11] selective operative management has become the prevalent approach to stab wounds of the abdomen and lower chest. Serial physical examinations have been suggested as the basis for selection.[12,13] Lee et al.[13] found serial physical examinations to be reliable in 88.6% with a negative laparotomy rate of 7.8%. Others have found physical examination less reliable and sought to use ancillary measures to arrive at an earlier diagnosis.

Local exploration of the wound may be a useful screening measure for abdominal stab wounds, but its use in chest wounds is less informative and it may also induce pneumothorax. Peritoneal lavage is the most popular ancillary measure, and its application has been championed in several series.[14,15] Using lavage Thal[14] in 213 out of 412 patients with abdominal and lower thoracic stab wounds had nine negative laparotomies among 412 patients; the false-negative lavage rate was 4.2%.

Feliciano et al.[15] in the largest series of peritoneal lavages for abdominal stab wounds reported a 91.2% accuracy for lavage in patients with peritoneal penetration but no abdominal sign. However, there were 37 negative laparotomies performed per year during the 4 years duration of the study, making the negative laparotomy rate for the 1150 patients with abdominal penetration 12.86%. Also, the value of peritoneal lavage in diagnosing diaphragmatic injury is challenged.[16] Thoracoscopy[17] and peritoneoscopy[18] have been advocated as methods of selection of patients for operative intervention, but they are cumbersome and have not been adopted on any large scale.

At Harlem Hospital Center, serial physical examinations have been the basis of selective operative management for stab wounds of the abdomen and lower chest during the last 10 years. In reviewing the cases managed during July 1981 through June 1986 we found that all of the diaphragmatic injuries due to stab wounds and 95% of those due to gunshot wounds fell within the boundaries of the region we have outlined as the thoracoabdominal region. The incidence of transdiaphragmatic injury for stab wounds of this region was 11.1%. We subdivided the region into 12 zones to see if the incidence for any one zone was high enough to justify mandatory laparotomy. The highest rate of transdiaphragmatic injury was found in wounds of the left anterior lower thoracic zone (21.7%), but even this incidence is too low to justify mandatory laparotomy. For the entire lower thorax stab wounds, transdiaphragmatic penetration rate in this series was 12.9%. Physical examination was accurate in selecting appropriate methods of management in 95.5% of patients. We used peritoneal lavage only in equivocal cases and in those with an altered sensorium. Our recent experience with ultrasonography has encouraged us to include it in our algorithm (Fig. 2) for managing wounds of the thoracoabdominal region. Delay in making the diagnosis based on physical examinations was not associated with mortality. Among the 56 patients managed by laparotomies five (8.9%) tested negative. The overall negative laparotomy rate for all patients with stab wounds of the thoracoabdominal region was 1.54%.

Although the true incidence of transdiaphragmatic injury in stab wounds of the thoracoabdominal region can only be determined by meticulous mandatory laparotomy, the results of this study suggest that selective laparotomy based on serial physical examinations supplemented by the judicious use of ancillary measures when necessary is an accurate and safe method of diagnosis and management of thoracoabdominal stab wounds.

Microbial Colonization of Tumors in Relation to the Upper Gastrointestinal Tract in Patients with Gastric Carcinoma

SVANTE SJÖSTEDT,* LARS KAGER,* ANDERS HEIMDAHL,† and CARL ERIK NORD‡

From the Department of Surgery,* Oral Surgery,† Huddinge University Hospital, Huddinge, Sweden, and the National Bacteriological Laboratory,‡ Stockholm, Sweden

The microbial colonization of the oropharynx, the esophagus, the stomach, and the duodenum was studied in relation to the microbial flora found on tumor and gastric mucosal biopsies in 23 patients with gastric carcinoma. The tumor was colonized in all patients, and the stomach, the esophagus, the duodenum, and the gastric mucosa were colonized in 96%, 87%, 83%, and 78% of the patients, respectively. The most common microorganisms isolated were *streptococci, bifidobacteria, lactobacilli,* and *Bacteroides* species, belonging to the normal oropharyngeal flora. Microbial colonization with gram-negative rods, *Clostridium* species or yeasts, was present in at least one site in 91% of the patients. *Clostridium* species were isolated from 57% of the patients. The total numbers of microorganisms recovered from the tumor biopsies did not vary with the intraluminal gastric pH. A relation between the gastric pH and the total number of microorganisms in the gastric juice existed. Significant higher numbers of different strains of microorganisms ($p < 0.005$) colonized the tumor compared to the gastric mucosa. Anaerobic microorganisms colonized the tumor significantly more often than the mucosa ($p < 0.001$). Antibiotic agents used as prophylaxis in gastric cancer surgery should cover both aerobic and anaerobic microorganisms, including *B. fragilis.*

PATIENTS with gastric carcinoma undergoing surgery are at high risk of developing postoperative infectious complications. The risk of infection is related to the density of the microbial colonization of the stomach, and the microorganisms causing infections are usually present in the stomach at the time of operation.[1,2]

The luminal floras of the oropharynx, the esophagus and the stomach, have previously been studied in patients with different diseases of the stomach by Sjöstedt et al. (Table 1).[3] Patients with gastritis, a history of previous gastric resection, and gastric carcinoma were found to have the highest pH of the gastric fluid and also to harbor more microorganisms in the stomach. Patients with gastric carcinoma were found to harbor the largest numbers of different microbial species and also more species not belonging to the normal oropharyngeal microflora than patients with any other gastric diseases. Patients with gastric carcinoma are almost invariably colonized in the stomach with microorganisms derived from the normal oropharyngeal flora but also often with enteric gram-negatives and yeasts. These patients have also been found to harbor anaerobes such as *Clostridium* species and *Bacteroides* species, including *B. fragilis,* in the stomach.[1-4]

In previous reports the microflora has been studied by means of aspiration of the intraluminal content. In this study not only the luminal flora of the oropharynx, the esophagus, the stomach, and the duodenum were studied, but also the microbial colonization of the tumor itself, which was compared with the normal gastric mucosa in patients with carcinoma of the stomach.

Materials and Methods

Twenty-three patients, 20 men and 3 females (mean age: 68.5 years) were studied. They all had histologically verified gastric carcinoma diagnosed at an earlier endoscopy. The samples for microbiologic analysis were obtained during an endoscopy performed as a part of the preoperative evaluation of the patient.

Before endoscopy, mixed saliva samples of 1 mL were collected by the patient spitting into a sterile glass tube.

Samples of 1 mL of fluid from the esophagus, the stomach, and the duodenum were collected during endoscopy by means of aspiration through a sterile polyethylene tube introduced into the biopsy channel of the

TABLE 1. *Numbers of Microorganisms Isolated from the Upper Gastrointestinal Tract in Patients Without Gastric Disease*[3]

Microorganisms	Log Numbers of Microorganisms/mL: Oropharynx	Esophagus	Stomach
Aerobic species			
Micrococci, staphylococci	9×10^7	0	$<10^2$
Hemophilus neisseria	9.7×10^6	0	$<10^2$
Streptococci	7.4×10^7	$<10^3$	$<10^2$
Anaerobic species			
Bifidobacteria lactobacilli	3.1×10^6	$<10^2$	$<10^3$
Veillonella	3.3×10^7	$<10^2$	$<10^3$
Fusobacteria	6.5×10^5	0	0
Bacteroides	2.2×10^7	$<10^3$	$<10^3$

endoscope. To prevent contamination a new sterile tube was placed in the biopsy channel each time the endoscope was moved to a new site. In the esophagus and the duodenum 1 mL of sterile saline (0.9%) was first injected into the lumen and then aspirated, and by this technique a luminal washing was obtained. In the stomach it was always possible to collect 1 mL of gastric fluid without a luminal washing.

After all luminal samples had been obtained the tumor was located. Three biopsies from the visually unaffected mucosa as far away as possible from the tumor were obtained and placed in three glass tubes with sterile saline. With a new pair of biopsy-forceps three biopsies from the tumor were then taken and placed in three glass tubes with sterile saline. All samples were immediately transported to the laboratory and processed.

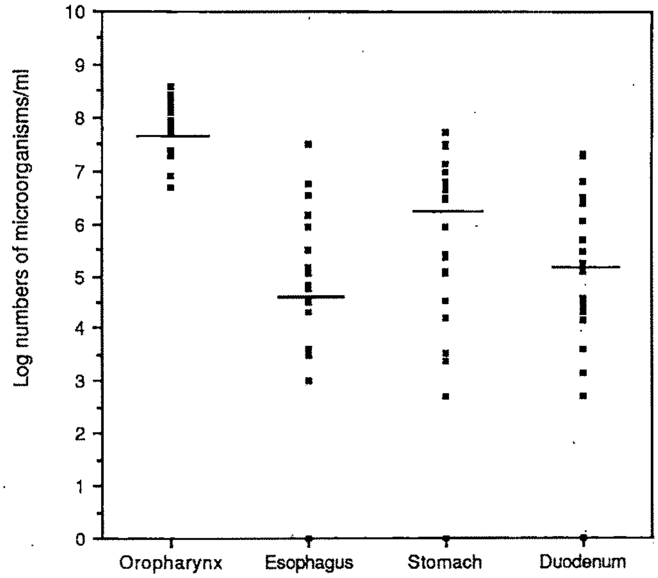

FIG. 1. Total numbers of microorganisms isolated from the oropharynx, esophagus, stomach, and duodenum in 23 patients with gastric carcinoma.

The samples of saliva, esophageal washings, gastric fluid, and duodenal washings were suspended in prereduced peptone yeast extract medium. They were diluted, inoculated on nonselective and selective media and manipulated as described by Heimdahl and Nord.[5]

The biopsies from the first 11 consecutive patients were cut into small pieces, homogenized, and then suspended in 4.5 mL prereduced peptone-yeast extract medium. Aliquots of 0.1 mL were then inoculated on selective and nonselective media.

In the other 12 consecutive patients a quantitation of the microflora isolated from the biopsies was also made. These biopsies were first weighed and then cut into small pieces, homogenized, and suspended in prereduced peptone-yeast extract medium. Tenfold serial dilutions were prepared to 10^{-4}. Each dilution was inoculated on nonselective and selective media.

The aerobic agar plates were incubated for 24 hours (luminal samples) or 48 hours (tissue samples) at 37 C, and the anaerobic agar plates for 2 days (luminal samples) or four days (tissue samples) at 37 C in an anaerobic chamber (Forma Scientific®, Marietta, OH).

Aerobic bacteria were identified as described by Heimdahl and Nord,[5] and anaerobic bacteria were identified using biochemical tests and gas-liquid chromatography.[6]

The pH of 4 mL of aspirated gastric juice was estimated using a pH-Meter 29 (Radiometer®, Copenhagen).

Statistical methods used were paired *t*-test and Fisher's exact test.

Results

Oropharynx

All patients harbored normal numbers (Table 1) of aerobic bacteria such as *streptococci, micrococci/staphylococci*, and *hemophilus/neisseria* and anerobic bacteria such as *bifidobacteria/lactobacilli, veillonella, fusobacteria*, and *bacteroides*. The median total counts of microorganisms were 7.0×10^7/mL (Fig. 1). Microorganisms not belonging to the indigenous oropharyngeal flora were colonizing 17/23 (73.9%) of the patients. *Clostridium* species were found in 39.1%, gram-negative aerobic rods in 30.4%, and yeasts in 21.7% of the patients (Tables 2 and 3).

Esophagus

The total counts of microorganisms were lower than in the oropharynx (median: 6.0×10^4 microorganisms/mL) (Fig. 1). Colonization of the esophagus was found in 20/23 (87%) of the patients. *Streptococci* were found in 87%, *micrococci/staphylococci* in 60.9%, and *bifido-*

TABLE 2. *Colonization with Microorganisms not Belonging to the Indigenous Oropharyngeal Microflora in 23 Patients with Gastric Cancer*

	No. of Patients Colonized

* Nonidentified gram-negative rods colonized the tumor in one patient.

bacteria/lactobacilli in 52.2% of the patients. Aerobic gram-negative rods did not colonize the esophagus, but *Clostridium* species were found in 13%, yeasts in 8.7%, and *enterococci* in 4.3% of the patients (Tables 2 and 3).

Stomach

The luminal gastric flora had a higher concentration of microorganisms (median total counts of microorganisms: 3.0×10^6/mL) than the esophageal flora but not as high as the oropharyngeal flora (Fig. 1). Twenty-two (95.7%) of the patients harbored microorganisms in the gastric juice. There was a clear correlation between the total numbers of microorganisms and the pH of the gastric juice (Fig. 2). *Streptococci* were found in 87%, *bifidobacteria/lactobacilli* in 78.3%, and *micrococci/staphylococci* in 60.9% of the patients. Microorganisms not belonging to the normal oropharyngeal microflora were found in 11/23 (47.8%) of the patients. *Clostridium* species were found in 21.7%, aerobic gram-negatives rods in 21.7%, yeasts in 13.0%, and *enterococci* in 4.3% of the patients (Tables 2 and 3). In only two patients did these microorganisms also colonize the oropharynx.

Duodenum

The median total counts of microorganisms were 1.0×10^5/mL (Fig. 1). Microbial colonization was found in 19/23 (82.6%) of the patients. *Bifidobacteria/lactobacilli* were found in 65.2%, *streptococci* in 60.9%, and *veillonella* in 43.5% of the patients. Microorganisms not belonging to the normal oropharyngeal flora were found in 11/23 (47.8%) of the patients. *Clostridium* species colonized 30.4%, aerobic gram-negative rods 17.4%, yeasts 13.0%, and *enterococci* 4.3% of the patients (Tables 2 and 3).

* Normal oropharyngeal flora.

Values are given as % of patients colonized.

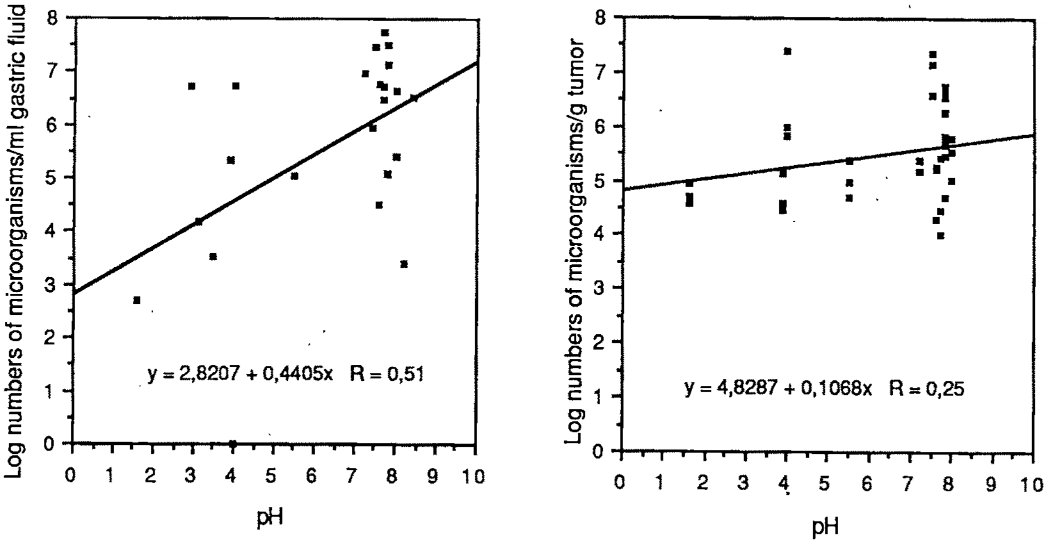

FIG. 2. (*left*) Relationship between total viable counts of microorganisms/mL gastric juice and gastric pH in 23 patients with gastric carcinoma. A significant correlation (r = 0.51) was found between increase in pH and numbers of microorganisms. The equation of the regression line is shown in the figure. (*right*) Relationship between total viable counts of microorganisms/g tumor tissue and gastric juice pH in 36 tumor biopsies from 12 patients with gastric carcinoma. No significant correlation was found (r = 0.25). The equation of the regression line is shown in the figure.

Gastric Mucosal Biopsies

Eighteen (78.3%) of the patients were colonized on the mucosal biopsies, and 17/23 (73.9%) had growth of aerobic microorganisms, and 7/23 (30.4%) had growth of anaerobic microorganisms. *Streptococci* (in 60.9% of the patients) and *micrococci/staphylococci* (in 43.3% of the patients) were the most common findings. Aerobic gram-negative rods were found in one patient (4.3%) and yeasts were found in another patient (4.3%). None of the patients was colonized with *Clostridium* species on the normal mucosa (Tables 2 and 3). The mean number of different strains was 2.9 on the mucosal biopsies (Table 4, Fig. 3).

Tumor Biopsies

All patients were colonized on the tumor and 22/23 (95.7%) had growth of aerobes and 20/23 (87%) had growth of anaerobes. Anaerobic bacteria colonized the tumor significantly ($p < 0.001$) more often than they did the normal mucosa (Table 4). *Clostridium* species were found on the tumor in 26.9% of the patients, significantly ($p < 0.05$) more often than on the normal mucosa. *Streptococci* (in 60.9% of the patients) and *micrococci/staphylococci* (in 43.3% of the patients) were the most common findings (Tables 2 and 3). Ten (43.5%) of the patients were colonized with microorganisms not belonging to the normal oropharyngeal microflora. Aerobic gram-negative rods were found in 8.7% and yeasts in 4.3% of the patients. The mean number of different strains was 6.5 on the tumor biopsies, which was significantly ($p < 0.0005$) more than on the mucosal biopsies (Table 4, Fig. 3). The total counts of microorganisms on the tumor biopsies from patients with a pH of 4 or less did not differ from the patients with a higher pH (Fig. 2). The total numbers of microorganisms were 2–30 times higher on the tumor samples than on the mucosa samples in all but one patient.

Discussion

In this study, the microbial colonization of the oropharynx, the esophagus, the stomach, and the duodenum was compared with the colonization of the tumor and the gastric mucosa in patients with gastric carcinoma.

We have previously reported on the intraluminal flora of the upper gastrointestinal tract in patients with different gastric diseases including carcinoma.[3] The oropharynx of patients with carcinoma are colonized with gram-negative rods, *Clostridium* species, and yeasts. This is probably not due to their gastric disease because the same microbial colonization in patients with other gastric diseases and even in normal subjects was found.[3] *Clostridium* species, however, were only found in patients with carcinoma.

In the esophagus, the concentration of microorganisms was much lower than in the oropharynx. This can only in part be explained by the sampling procedure because the dilution of the esophageal fluid with 1 mL of saline cannot explain the fall in concentration from 10^7 microorganisms/mL in the oropharynx to 10^4 microorganisms/mL in the esophagus. Other factors influencing the density of the esophageal flora can be the peristalsis of the esophagus causing a rapid washout of the microbes, secretion from the mucosa resulting in a dilution with less ability for microbial attachment or local immunologic factors. It is noteworthy that gram-negative rods in no case were isolated from the esophagus whereas *Clostridium* species and yeasts were, which is in accordance with our previous findings.[3]

Reports of the findings of microorganisms in preoperative and peroperative gastric aspirates have been published. In an earlier study it was found that patients with gastric carcinoma have higher bacterial counts and are colonized with higher numbers of different species than patients with other gastric diseases.[3] Gatehouse et al.[1] found growth of microorganisms in preoperative gastric aspirates in all of 35 patients investigated, and 54% of these patients had a total viable count greater than 5 × 10^6 organisms/mL, which is in an accordance with our findings. Muscraft et al.[4] investigated 31 patients with gastric carcinoma and compared them with patients with intact stomach receiving cimetidine and patients with resected stomachs. They found that *E. coli* (in 51% of the patients) and *Clostridium* species (in 25.8% of the patients) were more common in the carcinoma group. They also reported high frequencies of *Streptococcus fecalis* (70.9%) and *B. fragilis* (38.7%). In the present investigation these frequencies of *E. coli, S. fecalis,* or *B. fragilis* were not found, but a comparable frequency of *Clostridium* species of 21.7% and a frequency of *Bacteroides* species of 43.5% in the gastric aspirates were found.

The duodenal flora has not previously been studied in patients with gastric carcinoma. Normally, there is no permanent flora in the duodenum, but subjects with achlorhydria may be colonized with low numbers of microorganisms (median 10^3 microorganisms/mL). *Enterococci,* aerobic gram-negatives, oral aerobes and anaerobes and yeasts but not *Clostridium* species have been recovered.[7] We found a colonization in 82.6% of the patients and a median count of 1.0 × 10^5 microorganisms/mL; *Clostridium* species were found in 30.4% of the patients with gastric carcinoma.

No correlation between the colonization of the different sites of the gastrointestinal tract was found. For example, of the 11 patients colonized in the gastric aspirates with aerobic gram-negative rods, *Clostridium* species or yeasts, only two were colonized with the same microorganisms in the oropharynx.

It is generally agreed that there exists a relationship between the pH of the gastric fluid and the numbers of microorganisms in the gastric fluid.[3,4,8,9] Gastric aspirates with a pH of 4 or less are usually sterile. In this study, the colonization of the tumors, however, did not seem to be dependent of the pH of the gastric fluid. All patients with a pH of 4 or less were colonized on the tumor surface, and the total numbers of microorganisms did not differ significantly from the total numbers found on the tumors from patients with a higher pH. Consequently, the tumor may act as a reservoir on which the microorganisms may be protected from the acidity of the gastric juice and thus give rise to a continuous release of microorganisms into the gastric lumen. There were no significant differences between the species found in the intraluminal flora and the species found on the tumors.

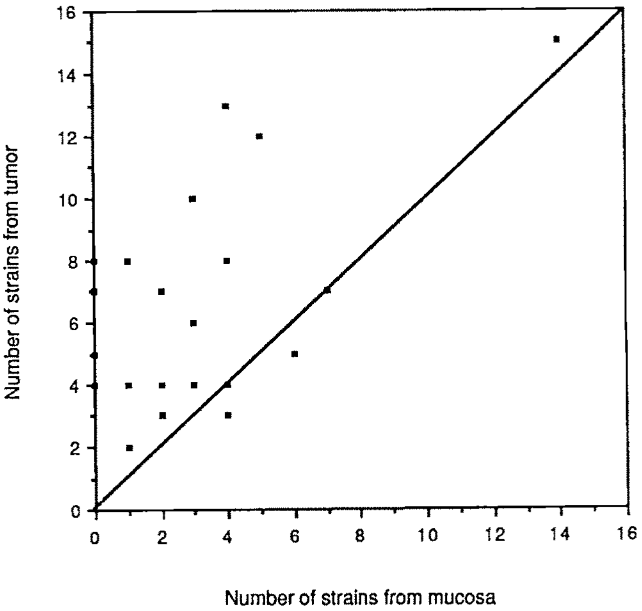

FIG. 3. The number of different predominant strains of microorganisms isolated from gastric mucosal biopsies in relation to the number of different strains isolated from tumor biopsies in 23 patients with gastric carcinoma. Points situated above the diagonal line indicate patients with a larger number of predominant strains on the tumor than on the mucosa. Points below the diagonal line indicate patients with a larger number of strains on the mucosa than on the tumor.

Some significant differences were found between the colonization of the mucosa and the tumors. Microorganisms were found in higher numbers on the tumors in all but one patient. Growth of microorganisms were found on tumor biopsies from all patients whereas the mucosa showed no growth at all in five patients. The numbers of different strains isolated from the tumor biopsies were significantly higher than the numbers of strains found on biopsies from the mucosa. Anaerobes seemed to have a strong tendency to grow on the tumors; *Bacteroides* species and *Clostridium* species could only be isolated from the tumors. The fact that the biopsies from the normal mucosa showed some colonization in most patients is surprising, but one explanation is that elderly patients often have various degrees of gastritis and that a damaged mucosa is more likely to be colonized.[10,11]

Clostridium species, including *C. perfringens,* seems to be the microorganisms, not belonging to the normal oropharyngeal flora, that are most likely to colonize the upper gastrointestinal tract of patients with gastric carcinoma. *Clostridium* species have in other studies been found to colonize patients with carcinoma of the colon[12] and patients undergoing bone marrow transplantation.[13] Overgrowth or colonization with *Clostridium* species may therefore in some way be associated with malignant disease.

Patients with gastric carcinoma are heavily colonized in the upper gastrointestinal tract, and microorganisms not belonging to the normal oropharyngeal flora can be found in most of the patients. These patients are at high risk of developing postoperative infectious complications, and previous reports have shown frequencies of between 13% and 56%.[1,15,16]

Cephalosporins have been recommended as antibiotic prophylaxis in gastric surgery since the study of Polk and Lopez-Mayor in 1969[17] and others.[18-23] In well-controlled studies, cephalosporins have been shown to significantly reduce the number of postoperative infections after gastric surgery. Stone et al.[19] used cefazolin and reduced the rate of postoperative infections from 22% to 4%. However, there is no study dealing specifically with prophylaxis in patients with gastric carcinoma. All studies include patients with various gastric diseases, and the number of patients with gastric carcinoma are often not stated. Keighley et al.[24] have reported on selective antibiotic prophylaxis in gastric surgery, including patients with gastric carcinoma. Only patients with total viable counts of $>10^6$ microorganisms/mL were given antibiotics. The choice of antibiotics was guided by the preoperative culture. The patients received ampicillin, gentamicin, clindamycin, or combinations of these agents. Full anaerobic coverage was judged to be appropriate in 10.5% of the patients receiving prophylaxis. Although this model of selective use of antibiotic prophylaxis was successful with an infection rate of 8%, it appears to be impractical. In the choice of antimicrobial agents for prophylaxis, simpler guidelines are needed.

Streptococci, staphylococci, enterococci, enterobacteria, Bacteroides species, including *B. fragilis,* and *Clostridium* species have been isolated from gastric aspirates in patients with gastric carcinoma. These microorganisms have also been isolated from postoperative infections after gastric surgery.[1-4,14-16,19,21] The present study has shown that in patients with gastric carcinoma the tumor itself is always colonized, often with anaerobic microorganisms, including *Bacteroides* species and *Clostridium* species.

From the present study and also from other studies it may be concluded that antimicrobial agents covering both aerobic and anaerobic bacteria, including *B. fragilis,* should be used as antibiotic prophylaxis in patients with gastric carcinoma undergoing surgery.

Results of Salvage Surgery for Mammary Recurrence Following Breast-conserving Therapy

JOHN M. KURTZ, M.D.,* ROBERT AMALRIC, M.D.,† HENRI BRANDONE, M.D.,† YVES AYME, M.D.,†
and JEAN-MAURICE SPITALIER, M.D.†

A retrospective analysis was performed of 118 surgically treated mammary recurrences, occurring following primary conservative excision and radiation therapy for clinical Stages I and II breast cancer. Actuarial cancer-specific survival following salvage surgery was 72% at 5 years and 58% at 10 years. With a median followup of 7 years, further local-regional recurrences were observed in 20 of the 118 patients, many of whom could be treated by further surgery. Actuarial survival after recurrence was significantly influenced by initial clinical stage, as well as by the disease-free interval following primary therapy, but was similar for both premenopausal and postmenopausal patients and for patients treated by radical or breast-conserving salvage operations. For recurrences after the fifth year, actuarial survival following salvage surgery was 83% and 68% at 5 and 10 years, respectively. Survival for Stage I patients was favorable regardless of disease-free interval. It is concluded that recurrences in the breast following primary treatment with limited surgery and irradiation have a considerably more favorable prognosis than that of local failures after primary radical surgery. Suggestions for the management of these recurrences are presented.

*From the Departments of Surgery and Radiotherapy, Cancer Institute, Marseille, France,† and the Department of Radiation Oncology, University Hospital, Basel, Switzerland**

THE TREATMENT of early mammary carcinoma with preservation of the affected breast has become commonplace during the past ten years largely due to encouraging reports from several treatment centers having long experience with conservative techniques.[1-8] The recent publication of three randomized clinical trials, moreover, has established the validity of this treatment approach,[9-11] and has assured that breast-conserving therapy will become even more widespread.

Although curative therapy of local recurrences following primary radical mastectomy is seldom successful,[12-16] available evidence suggests that the prognosis of breast recurrence after tumorectomy and irradiation is considerably more favorable.[3,17-20] Since the treated breast remains at risk for an indefinite period of time, it is apparent that the optimal detection and therapy of breast recurrences represents an important facet of conservative treatment strategy. Thus, it is remarkable that the surgical management of local recurrences after breast-conserving therapy has received virtually no attention in the literature.

After 25 years of experience with more than 5000 conservatively treated patients with operable mammary carcinoma, we have had the opportunity to treat a large number of local recurrences.[18] The purpose of this article is to analyze the results of salvage therapy after initial management by local tumor excision and irradiation, to attempt to define prognostic factors, and to provide guidelines for the management of recurrence in the treated breast.

Materials and Methods

In order to provide adequate follow-up time after treatment of recurrence, this report has been restricted to patients whose primary therapy took place prior to the end of 1980. Excluded from analysis were all patients treated after that date, all patients referred by outside physicians exclusively for management of recurrence, patients whose primary tumors measured greater than 5 cm in diameter, as well as 1483 patients with moderately advanced lesions treated during the same time period by radiation therapy alone, without excision of the primary tumor.[2,21] Remaining as the basis for this

Submitted for publication: July 23, 1987.

report were 1245 patients with operable breast cancers in clinical Stages I and II (American Joint Committee, 1983)[22] treated between January 1963 and December 1980 at the Cancer Institute and associated clinics in Marseille, employing breast-conserving surgery followed by curative radiation therapy. Treatment techniques and long-term results of therapy have been described in previous publications.[2,21,23] Briefly, primary surgical treatment consisted of simple lumpectomy or wedge excision of the primary tumor, with or without limited axillary dissection. Radiation was performed using a telecesium or telecobalt unit, delivering 50–60 Gy (5000–6000 rad) to breast and regional nodes, followed by supplemental external beam irradiation to the tumor bed (20–30 Gy) and lower axilla (10–20 Gy).

Prior to January 1987, 143 of these 1245 patients (11.5%) developed recurrence in the treated breast. An additional 24 patients developed isolated recurrence in the ipsilateral axilla, and will not be considered further here. In 19 of the 143 patients (13.3%), a secondary operation was not performed, either because of the presence of distant metastases (11 patients), patient or physician preference (4 patients), or due to the local extent of the disease (4 patients). One hundred twenty-four patients were subjected to secondary operations for histologically proven breast recurrence, in the hopes of obtaining another chance at cure (salvage surgery). This report is restricted to 118 patients having had salvage surgery prior to December 1985.

Of the 118 patients having salvage surgery for proven recurrence, 56 were initially in clinical Stage I (T_1 N0) and 62 initially in clinical Stage II (T_1 N1 or T_2 N0-1). The average age of the patients at the time of primary treatment was 47 years. The mean interval between primary therapy and recurrence was 61 months. One hundred fourteen of the recurrences (96.6%) were described as being close to the site of the original primary tumor.

Salvage surgery consisted in 66 instances of a mutilating operation, either a simple mastectomy (8 patients), radical mastectomy (19 patients), or a modified radical mastectomy (39 patients). In 52 patients the salvage operation was conservative, consisting of wide excision in 34 patients and wide excision with axillary dissection in 18 patients. Conservative salvage surgery was introduced during the 1970s and has been increasingly employed for the treatment of isolated, small breast recurrences showing no signs of rapid growth. Although adjuvant hormone treatment was administered to selected patients, chemotherapy at time of breast recurrence was seldom employed.

Follow-up from time of salvage surgery ranged from 12 months to 20 years (median: 7 yr). Statistical analysis was performed using the life-table method of Kaplan and Meier.[24] Survival was calculated in terms of actuarial cancer-specific survival rates (hereafter referred to as actuarial survival), with patients dying of intercurrent causes while disease-free treated as censored observations at time of death. Patients dying of unknown cause were assumed to have died of cancer. The logrank test was employed to evaluate the differences between survival curves.[25]

Results

At the time of this analysis (January 1987), 34 of the 118 patients (29%) have developed proven distant metastases, and 38 patients have died, including 2 of intercurrent disease and 5 of unknown causes. The actuarial survival from time of salvage surgery was 72% at 5 years, and 58% at 10 and 15 years (Fig. 1).

With a median follow-up of 7 years after salvage surgery, 20 patients are known to have developed a second local or regional recurrence in the breast, chest wall, or axilla with or without the presence of distant metastases. This includes 8 of the 66 patients (12.1%) having had a secondary breast amputation and 12 of the 52 patients (23%) having been treated by breast-conserving salvage operations. Second recurrences after conservative salvage surgery could be treated by tertiary operations in ten instances.

Prognostic factors were investigated employing actuarial survival following the time of salvage surgery. The following parameters were analyzed (Table 1): age at time of primary therapy (less than 50 *vs.* 50 or greater, as a measure of menopausal status); initial clinical stage (I *vs.* II); histologic lymph node status at time of salvage surgery (positive *vs.* negative or undetermined); disease-free interval between primary therapy and recurrence (less than 3 years *vs.* 3–5 years *vs.* more than 5 years); and type of salvage operation (mastectomy *vs.* breast-conserving). Age and type of salvage operation had no significant correlation with the prognosis of breast recurrence. The slight advantage for patients treated by conservative salvage surgery may be explainable by the favorable selection of patients for these operations.

Disease-free interval and initial clinical stage represent the most significant prognostic factors for survival following breast recurrence. The outlook for recurrences occurring after the fifth year is significantly more favorable than that of recurrences operated prior to 3 years (Table 1). The prognosis of operable local recurrence in clinical Stage I patients was favorable even if the recurrence occurred prior to 5 years (5- and 10-year actuarial survival after salvage surgery: 70% and 65%, respectively, N = 28). For patients failing prior to 5 years, the unfavorable influence of axillary involvement at time of recurrence was statistically significant (5- and 10-year

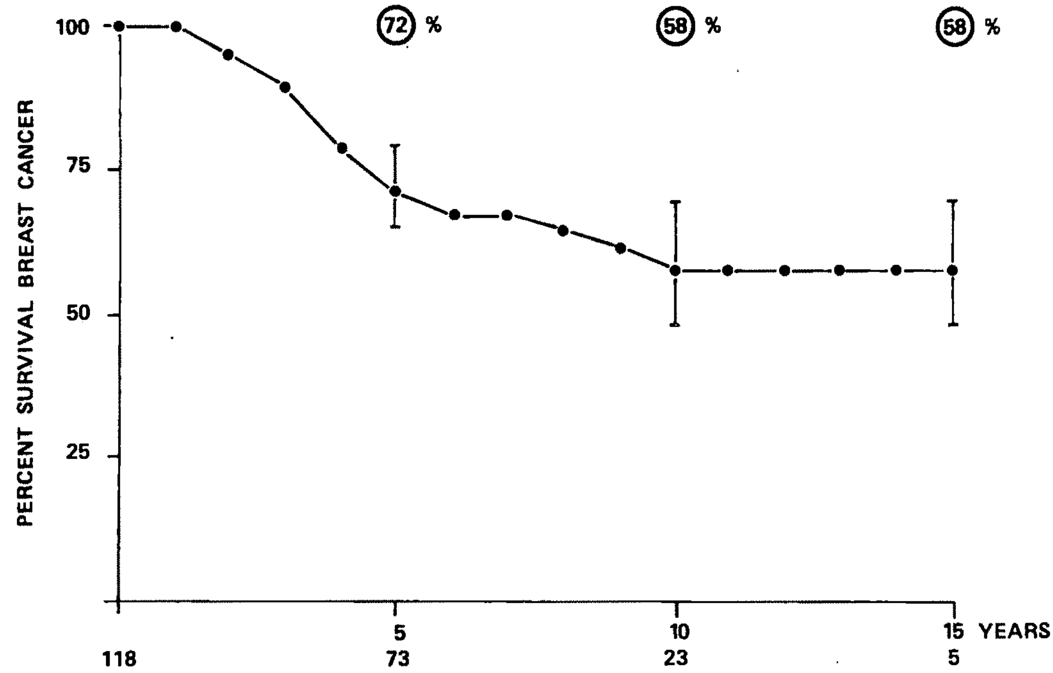

FIG. 1. Actuarial cancer-specific survival measured from the time of salvage surgery for mammary recurrence. The error bars represent the 95% confidence limits at 5, 10, and 15 years. The numbers at the bottom represent the number of patients alive at the beginning of the corresponding intervals.

actuarial survival after salvage surgery: 65% and 41%, respectively, N = 20) when compared to clinical Stage I patients with recurrences confined to the breast (5- and 10-year actuarial survival after salvage surgery: both 84%, N = 20, p value less than 0.01).

Discussion

Following treatment by primary radical surgery, the diagnosis of recurrence on the chest wall or in regional nodal areas connotes a grave prognosis for the breast cancer patient. Approximately one third of such patients have distant metastases diagnosed concomitantly with local recurrence, and the remaining patients who undergo *curative* treatment with surgery and radiotherapy have a poor outlook. Further therapy results in control of local disease in only about 50% of patients. Moreover, the majority of patients treated for apparently isolated local recurrence die of distant metastases, with overall survivals ranging from 21–38% at 5 years and 5–26% at 10 years.[12–16] Prevention of such recurrences through the use of adjuvant postoperative radiation therapy has failed to significantly improve survival rates,[26] suggesting that the appearance of local failure following primary radical surgery is the expression of a more aggressive tumor biology.

Such conclusions, however, do not necessarily apply to local recurrences following breast-conserving therapy. First, the percentage of inoperable recurrences is relatively small, with a range of 10–25% from the literature.[18] The high percentage of operable recurrences in our series (87%) probably reflects in part our program of follow-up examinations aimed at the early detection of such recurrences.[23] Second, local control following salvage surgery for recurrence after conservative therapy has been very satisfactory, with only 17% of our patients thus far having developed further local or regional disease manifestations. Although local control appears superior with secondary mastectomy, most patients having second recurrence following breast-conserving salvage surgery could be subjected to tertiary operations, and some have remained disease free. Follow-up is too

short, however, to render judgment on the effectiveness of tertiary salvage surgery. If one includes the 19 patients not receiving salvage surgery, a total of 39 of the 1245 patients (3.1%) in this series had their breast disease uncontrolled by primary or secondary treatment. These results suggest that the combination of limited surgery and irradiation, with further surgery held in reserve in case of recurrence, provides control of local disease at least as good as that achieved by primary radical surgery.

A further contrast with postmastectomy recurrence is provided by the survival analysis of our patients, 72% of whom survived 5 years and 58% for 10 years following surgical treatment of recurrence. Actuarial breast cancer-specific survival appears to plateau after 10 years, suggesting that many patients may be cured by the salvage operation. It is likely, therefore, that local recurrence reflects a more virulent disease process only for a relatively small subset of patients, and that for many patients the disease course is not influenced by the appearance of failure in the breast. In particular, conservatively treated Stage I patients continue to have a favorable prognosis despite local recurrence.

Our analysis of prognostic indicators demonstrates that the disease-free interval between primary treatment and recurrence is a very significant determinant of survival following salvage therapy. The importance of disease-free interval has previously been well documented in analyses of recurrences following radical surgical therapy.[13–15] Since the treated breast remains at risk for recurrence for an indefinite period, it is possible that late local recurrence will be observed more commonly following breast-conserving therapy than after primary radical surgery. Thus, it is important to realize that local failure after the fifth year has a very favorable prognosis, with actuarial survival of 68% 10 years following treatment of recurrence. We have found that such late recurrences have a significantly better prognosis than that of contralateral breast cancer in this series of patients (Spitalier J-M, Kurtz JM: unpublished observation, January 1987). The continued risk of ipsilateral breast recurrence beyond 5 years, therefore, does not represent a cogent argument against breast preservation. We do not expect that late recurrences will in any way prejudice the current early results favoring this form of treatment.[9–11] The distinction between late recurrence and *new* tumor formation in the ipsilateral breast is extremely difficult, and may be mainly of academic interest. This will be the subject of a subsequent report.

Prognosis of breast recurrence during the first 5 years appears to depend to a large extent upon the status of the axilla. The outlook is unfavorable for patients initially in clinical Stage II, as well as for patients having histologically involved axillary nodes at time of salvage surgery. Thus, patients having been initially at high risk for axillary metastases, or those having suffered proven recurrence in the axilla, have a poorer prognosis than early-stage patients, or those developing recurrence confined to the breast. These results confirm our previous observations,[18] as well as those of Clark et al., who showed that isolated breast recurrence had no significant impact on the course of the disease in the Toronto series.[17] Since the majority of our patients did not have axillary dissection at the time of initial therapy, a more precise evaluation of the prognostic significance of nodal status is not possible.

There are no published guidelines for the management of recurrence following breast-conserving therapy, perhaps reflecting a supposition that failure in the breast dictates mastectomy. We have found that wide excision of selected localized breast recurrences, however, can be associated with satisfactory results.[27] Patients desiring a second chance at breast preservation may be offered this treatment option, provided that the recurrence is 2 cm or smaller in diameter, mobile, and without signs of rapid growth or extensive axillary adenopathy. Many of the 20–30% of patients developing second breast recurrence after conservative salvage surgery can be offered a potentially curative tertiary operation. Less favorable recurrences should be treated by total mastectomy. Independent of the treatment of the breast, the axilla should be dissected at the time of mammary recurrence, provided that it had been previously undissected or if clinically suspicious findings are present. Isolated axillary failure should be treated by axillary dissection if there is no clinical or radiographic evidence for recurrence in the breast.

The role of adjuvant medical therapy at time of local failure has never been formally investigated, and such treatment has not been employed in any consistent fashion in our institution. Additional therapy following surgery for late recurrence is generally unnecessary. For the less favorable recurrences occurring during the first 5 years, especially those with axillary failure or prior evidence of lymph node involvement, adjuvant systemic treatment is generally recommended, although evidence for its efficacy in this setting is lacking. The hormone receptor status and age of the patient dictates whether oophorectomy, hormone therapy, or combination chemotherapy is employed as adjuvant treatment.

Cope's Early Diagnosis of the Acute Abdomen, 17th ed. William Silen. 290 pp. New York: Oxford University Press. 1987. $14.95.

I HAVE a large library of surgical texts and refer to them often. I have and value the charming *The Acute Abdomen in Rhyme* by the pseudonymous *Zeta* who is well known to have been Sir Zachary Cope. Cope's classic *Early Diagnosis of the Acute Abdomen* is now in its 17th edition, and but for the good fortune of having been asked to review it, I should still be ignorant of this gem now in its second edition in the capable hands of William Silen. I had known of the book—of course, who has not—but considered from first hearing of it that a book with that title did not have much to teach me. How wrong I was!

The book is a model of simplicity, lucidity, and soundness, and the language is a joy. Perhaps senior surgeons will consider that Cope and Silen are preaching to the converted. For them I will say that it may well be that a reading of this little book will show them an example of how really to teach. As for students and house officers, let them learn how really to make a diagnosis and how much can be learned from history and sophisticated physical diagnosis before, and often without, resorting to the modern panoply of diagnostic equipment, as well as the when, why, and which of such resort.

A few quotations will transmit the marvelous flavor. "The pulse is too optimistic a friend to be relied upon for guidance either in diagnosis or prognosis in the early stages of abdominal disease . . . many if not most, patients with acute lesions of the abdomen have a normal pulse during the early stage. . . ."

"In many medical centers, there are standard algorithms for laboratory and radiologic investigations . . . patients with abdominal pain receive many unnecessary, expensive and sometimes misleading laboratory tests. . . . It is imperative that the clinician understand that *laboratory tests will never substitute for clinical evaluations of the patients* . . . x-ray studies are *not* necessary or desirable in all patients with abdominal pain." Lives would be saved if every medical student in the United States read and remembered the statement that in *colic* whether intestinal, urinary or biliary, "though occasionally rigid during the paroxysms the abdominal wall is soft between bouts of pain."

Easy to read and full of good sense, the book is a distillation of the massive clinical experience of two master surgeons. Abundant line drawings and reproductions of roentgenograms and sonograms illustrate the text, which is unencumbered by graphs, tables, formulas, statistics, or references. The experienced surgeon will enjoy comparing his own opinions, procedures, and priorities with those of Cope and Silen. The less experienced are not likely to find anywhere so much useful wisdom in so few pages.

Pittsburgh, Pennsylvania

Surgical Application of Lasers, 2nd ed. John A. Dixon. 376 pp. Chicago: Year Book Medical Publishers. 1987. $49.95.

THIS MONOGRAPH is edited by Dr. John A. Dixon who is clearly the leader in the use of lasers in medicine and surgery. He has been a major force in the education of physicians and surgeons concerning the use of lasers in clinical practice, and the second edition of this monograph continues that tradition. As with the first volume, it provides the background for clinical use of lasers in surgery. In addition, it contains an excellent update of developments in this advancing field during the past 5 years. Twenty other clinical laser specialists have contributed to this text, which again reviews the basic science of laser technology and then discusses its use in various surgical disciplines.

The chapters on historical background and instrumentation are well done, and the basic science section is complete and quite readable. In the section on safety, Dr. Dixon emphasizes the dangers of lasers and the need for consistent observation of appropriate precautions when using lasers. The points regarding establishing a laser system in the institution are important and helpful.

Dr. Dixon and the other contributors have had a wide and successful clinical experience. The clinical sections are commendably complete, and the most recent advances are cited as well as problems that need to be addressed in each specialty. The chapter on photodynamic therapy is excellent and is an important component.

The illustrations are quite good, and the color plates that are included in one section might well have preferentially been placed with the specific chapters to which they apply. In summary, this monograph brings the reader up-to-date on the developments in laser therapy during the past 5 years, and the editor has achieved this goal admirably.

Walter G. Wolfe, M.D.
Durham, North Carolina

Essentials of Plastic, Maxillofacial, and Reconstructive Surgery. Nicholas G. Georgiade, Gregory S. Georgiade, Ronald Riefkohl, and William J. Barwick. 1189 pp. Baltimore: Williams & Wilkins. 1987. $117.95.

THIS IS AN ambitious attempt to cover in one volume the entire field of plastic surgery. The four authors, all from Duke University, have collected input from 133 contributors and molded it into an informative, readable, and comfortable volume. Fortunately, the inevitable unevenness in the quality of the chapters has been minimized, probably due to "the strong hand of the principal editor, Dr. Nicholas G. Georgiade," to quote from the foreword by David C. Sabiston, Jr., M.D.

The book is divided into nine sections: Basic Principles, Skin and Soft Tissues, Head and Neck, Aesthetic Surgery, Breast Surgery, Surgery of Genitalia, Microsurgery, Trunk and Lower Extremity, and Practical Concepts of Plastic Surgery Practice.

The 94 chapters are written with as much detail as could be expected in such a comprehensive volume. The drawings, tables, and sketches have been selected effectively to amplify the text without cluttering it. None of the chapters is monographic in scope, but the bibliographies are selective and mostly current.

The two sections on Head and Neck (388 pages) and Microsurgery (234 pages) occupy over half the book and reflect the major interests and contributions of the Duke unit. The section on Breast, another area of their special interest, is well presented. The embryologic descriptions in several of the sections are noteworthy.

This text will be useful for all residents and practitioners in plastic, maxillofacial, and oral surgery. They will find it a convenient final source for some subjects, and a valuable starting point for the others. The price of $117.95 seems reasonable.

JOSEPH E. MURRAY, M.D.
Boston, Massachusetts

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

Title page
Abstract and key words
Text
Acknowledgments
References
Tables: each table, complete with title and footnotes, on a separate page
Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

Key Issues, Article 1, 2/88
Series: Deep Vein Thrombosis

Risk Assessment/Selected Treatment: Answering the DVT Challenge

The numbers paint a sobering picture. Deep Vein Thrombosis (DVT), often the precursor of pulmonary embolism, occurs 2.5 million times a year in the U.S. Between 300,000 and 600,000 hospitalizations are a direct result. Approximately 150,000 deaths annually are traced to pulmonary embolism.

Even more sobering is the recent clinical evidence and expert opinion that this toll is far too high. Studies indicate that 50-75% of DVT occurrences can be prevented by a regimen of risk assessment and selected treatment.

A Consensus Development Conference of the National Institutes of Health reported that the most effective method of preventing the incidence of DVT is to assess patient risk factors and determine the appropriate prophylactic regimen. Such a plan would set forth a range of non-invasive and pharmaceutical options, from which physicians would choose the elements that best fit an individual patient's condition.

This process begins with risk assessment. Clinical research has identified the principal factors that affect DVT incidence.

Low Risk	Under 40 years of age, minor surgery, uncomplicated medical condition, no DVT/PE history.
Moderate Risk 6-40%	Over 40 years old; abdominal, pelvic or thoracic surgery, uncomplicated myocardial infarction.
High Risk Over 40%	Over 40 years old, with previous DVT/PE history, malignant diseases, extensive general surgery or hip replacement, other high-risk patient attributes.

The validity of risk assessment arises from the silent nature of DVT. In fact, up to two thirds (⅔) of the real incidence of DVT often go undetected. Stasis, coagulation changes and blood vessel damage are the principal causes. Consequently, factors such as age, immobility, obesity and other medical conditions that can contribute to causal ingredients can be clearly identified.

Selected treatment establishes a level of intervention appropriate for the patient's risk level. Both physical (non-invasive) or pharmaceutical approaches are available.

	PHYSICAL	PHARMACEUTICAL
Methods	Elevation T.E.D.® Anti-Embolism Stockings SCD™ Sequential Compression Device Early Ambulation	Heparin Coumadin Warfarin
Effects	Overcomes stasis by mechanically promoting adequate venous return	Alters blood coagulation chemistry to inhibit clotting tendency
Considerations	Noninvasive No side effects known, clinically proven effective	Requires laboratory monitoring Potential bleeding complications

According to the NIH Consensus Development Conference report, the use of physical approaches, such as elevation of the bed, graduated compression stockings and sequential pneumatic compression can reduce the incidence of DVT significantly. The use of these mechanical measures is without known complications. The use of pharmaceuticals in many instances also drew favorable comment from the report.

In effect, the evidence supports establishing clinical guidelines including physical approaches to prophylaxis. At higher levels of risk and where side effects are not at issue, pharmaceuticals can provide an added measure of effect.

The fact is that whatever format of risk assessment and menu of selected treatment a hospital chooses, prophylaxis works to reduce the incidence of DVT and associated pulmonary embolism with dramatic effect. We now have the tools to answer the DVT challenge.

(Kendall can provide a wide variety of informational and educational materials on DVT prevention as well as in-hospital programs. To answer your needs, please contact: Kendall Healthcare Products Company, 15 Hampshire Street, Mansfield, MA 02048)

The Challenge of DVT:
Step One

T.E.D./SCD

*THE EVIDENCE IS IN.
Prophylaxis works against
Deep Vein Thrombosis.
Major Reductions in
occurrence and significant
cost savings.*

T.E.D.® Anti-Embolism Stockings provide a first step in a prophylactic program. For all patients – low, moderate and high risk. They provide the first line of defense against venous stasis – a key factor in DVT development – and can be used effectively with Kendall's SCD™ Sequential Compression Device.

Together, they provide both static and dynamic compression. The static compression of T.E.D. Anti-Embolism Stockings works to provide continued patient protection over extended periods of risk. The Sequential Compression Device provides dynamic compression for periods of increased risk.

Both offer distinct advantages.

The SCD sequential graduated pneumatic compression device performs to produce peak blood flow velocity over conventional uniform devices.

And T.E.D. Stockings. They're simply the leader. Because of their optimal pressure gradient which enhances blood flow velocity. What is really important though, is that they are still the one and only graduated compression stocking clinically proven to reduce the incidence of venous thrombosis.

The cost? Negative. Because T.E.D. Anti-Embolism Stockings and the SCD Sequential Compression Device perform to lessen DVT treatment costs. Together or separately.

We'd be happy to send you the evidence behind that claim. Just write to:

TUCKS®

Pre-Moistened Hemorrhoidal/Vaginal Pads

To change the course of anorectal therapy

Added to any anorectal regimen, TUCKS pads provide complementary benefits no single anorectal preparation alone can offer. TUCKS pads act instantly, on contact, to soothe, cool, and comfort tender, irritated anorectal tissue. And TUCKS cleanses as it soothes to gently remove potentially irritating fecal residue.

So the next time you're recommending an anorectal ointment, cream, or suppository, recommend the addition of TUCKS. It adds up to more effective anorectal therapy.

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV

(cefotetan disodium)

Does so much for so much less than cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,** *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,** *Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus.*†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

† Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

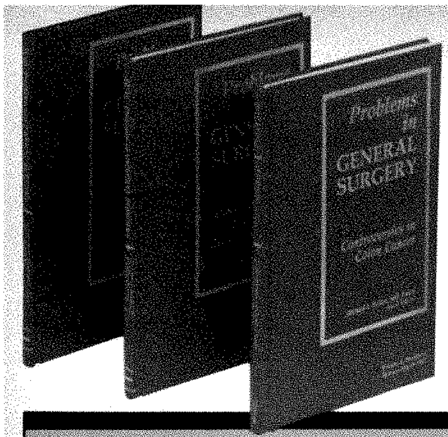
LIBRARY



Totally current data and opinion on surgical management of colorectal cancers

Three volumes in the respected *Problems in General Surgery* series bring you up-to-the minute information that you can use *today* in your practice. Articles with real clinical relevance. Succinct presentations of major differences of opinion. Starkly different points of view on diagnosis and treatment—the questions you face when you make life-and-death decisions. The best thinking of leading practitioners to help you make the choices of modality of treatment most appropriate for each patient.

Here are information and insights that will challenge you to do something different and better in your practice the day after finishing each volume.

Abundant illustrations, diagrams, tables, charts. Totally current references, with commentary. *Each volume $30.00. Annual subscription (4 volumes) $59.00 (U.S.), $68.00 (elsewhere).*

Send for the volumes you need today. And begin your subscription to this challenging series with the next volume.

CASE # 24 **AGE:** 55 **SEX:** FEMALE

DIAGNOSIS: CECAL CARCINOMA

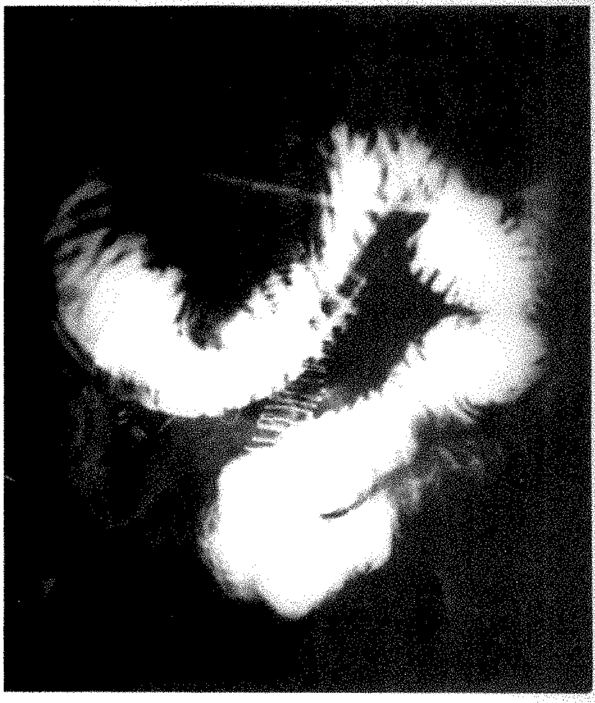
SYMPTOMS: ANEMIA (Hg 6 gm/dl)

OPERATION: RIGHT HEMICOLECTOMY & GASTROSTOMY

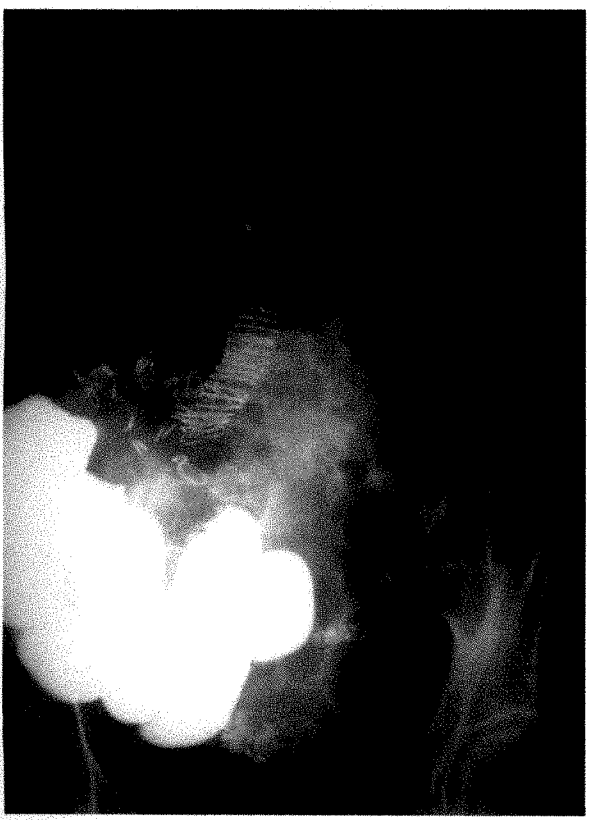
The patient had a right hemicolectomy with stapled (U.S. Surgical Corp) anastomosis and fascia closure and a MOSS® gastrostomy tube. The stomach and proximal duodenum were aspirated, with immediate simultaneous feeding into the distal duodenum.

Barium feeding 5 hours postop documented adequate motility. The deliberate excess was totally removed. No contrast (i.e.: excess feeding) escaped efficient aspiration within the proximal duodenum, to reflux into the stomach. (Figure A) Serial motility study showed barium had traversed the anastomosis and colon, and already was exiting in a spontaneous bowel movement by 21 hours postop. (Figure C)

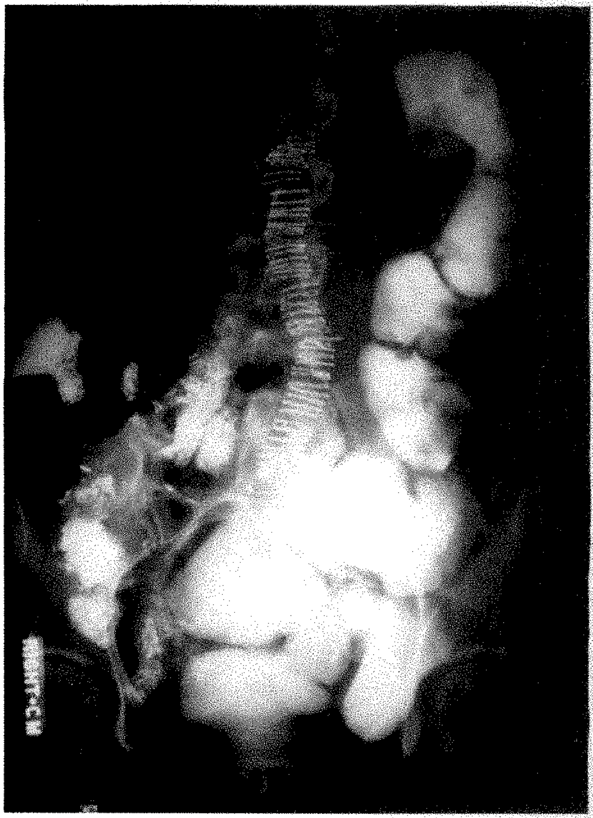
She received 300 ml/hr of Vivonex TEN (Norwich Eaton Pharm), absorbed 5,000 kcal the initial 20 hours, and then tolerated a general diet. She was the 4th patient discharged uneventfully 24 hours after bowel resection and reanastomosis.



A. Study @ 5 minutes (5 hours postop).
Note efficient removal of all excess barium, with none reaching the stomach.



B. Motility @ 4 hours (9 hours postop).
All barium is within the ileum.



C. Motility @ 16 hours (21 hours postop).
Barium is exiting in a spontaneous bowel movement.

Call MOSS TUBES, INC (518) 674-3109 for introductory sample and literature.

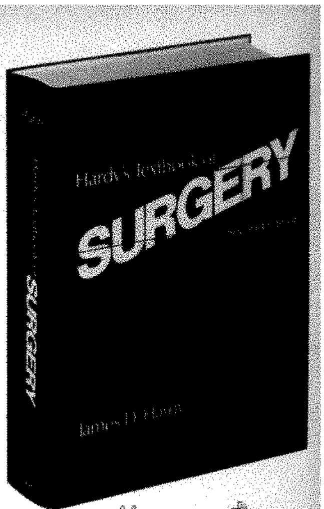
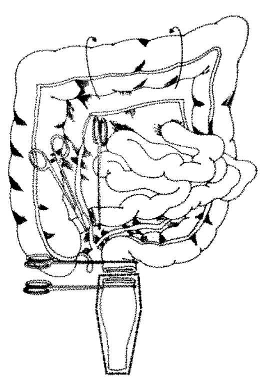
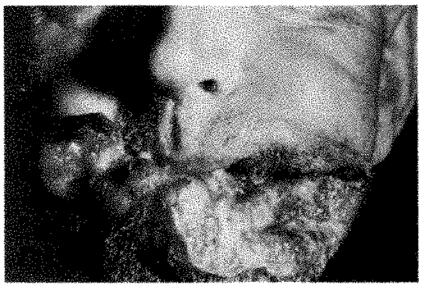
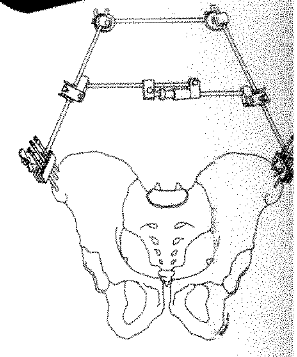
Letters to the Editor









NEW Second Edition!

Crisp, comprehensive
readable—all you need in
compact, practical form!

Hardy's Textbook of SURGERY

SECOND EDITION

Edited by **JAMES D. HARDY, M.D.**
with 119 Contributors

Concise, comprehensive, practical— and up to 40% shorter!

The notable features of the first edition of this remarkable text were its comprehensiveness and its concise treatment of the subject. These features have been retained and strengthened in the second edition—once again 30% to 40% shorter than other textbooks of surgery while scrupulously covering the basic principles of surgical diagnosis and treatment. Crisp. Pithy. Above all, highly *practical* as a day-to-day reference.

Tightly organized—you can review information rapidly

The book captures the principles of surgery in tightly written, rigorously organized chapters. Part One covers basic and support considerations, those aspects of the field that are applicable to any surgical procedure, such as patient response to surgery, shock and cardiac arrest, respiratory support, wound healing, infections, preoperative preparation, and anesthesia. Part Two is organized by specific organs and organ systems, and systematically describes surgical principles and procedures. Basic science discussions are confined to applied physiology and anatomy in specific clinical situations.

New in the Second Edition

- *all material reviewed, and much extensively rewritten*
- *several new contributors strengthen coverage in areas where major developments are taking place*
- *many new illustrations of operative technique*
- *completely new index*
- *completely new chapter on Response to Surgery*
- *new material and especially significant revisions in the chapters on Nutrition in Surgical Patients; Trauma; Anesthesia; The Breast; The Mesenteric Small Bowel; The Lung; Gynecologic Surgery; and the Appendix*
- *new sections on GI hormones and the gallbladder-biliary tract*
- *entirely rewritten chapter on Orthopaedic Surgery*

High Praise for the First Edition

"... concise, current, clinically relevant, and, moreover, readable ... commendably, Hardy and the contributing authors are cognizant of what general surgery entails today ... just may become the gold standard."

—*Mayo Clinic Proceedings*

"... an important addition to current general surgery textbooks ... comprehensive ... easy to read and review."

—*New England Journal of Medicine*

"... I commend the author for accomplishing his stated goals of providing a standard textbook of surgery that includes concise coverage of basic subjects of general surgery with appropriate supportive science and emphasis on what is clinically relevant. I heartily recommend this book."

—*Annals of Surgery*

About 1,440 Pages. 559 Illustrations. 170 Tables.
2nd Edition, 1988. Hardcover $55.00.
Flexible Binding $39.95.

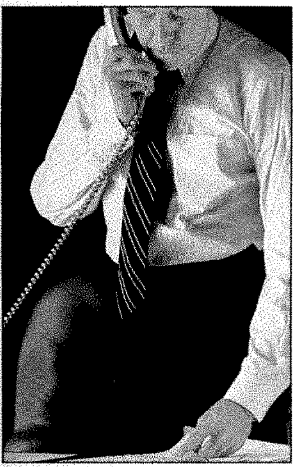
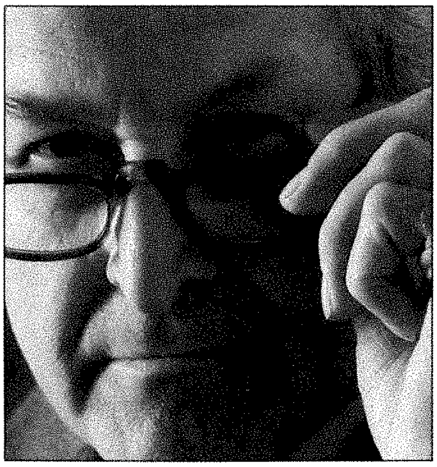
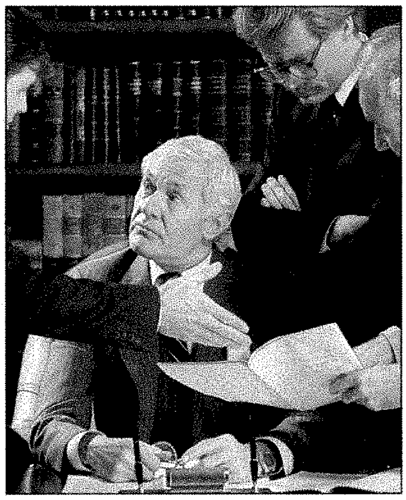
Do you really think he's going to sit still for a sitz bath?







Hemorrhoids: A Problem Worth Solving.

The evidence is overwhelming. Every year 123,000 Americans undergo painful hemorrhoidectomies.[1] Millions more suffer from symptoms of itching, bleeding, and tissue prolapse through the rectum.

Patients with symptomatic hemorrhoids want immediate relief and a real solution.

ULTROID™: A Clinically Proven Solution.[2]

Now with ULTROID, Microvasive® introduces the future of nonsurgical hemorrhoid management. It is a monopolar, low-voltage treatment modality, clinically evaluated on hundreds of patients. ULTROID works biochemically at the feeding vasculature of the hemorrhoid's base. It leaves no visible ulceration or scarring.

ULTROID: Safe, Painless, and Effective.

ULTROID is the only modality that works on all four grades of symptomatic internal and mixed hemorrhoids. It works without cauterization, without burning. It can be used in your office, without special patient preparation or anesthesia. And, with ULTROID, patients experience no postprocedure pain or lifestyle disruption.

ULTROID: The New Treatment of Choice.

For more information on this new hemorrhoid treatment, our physician-moderated seminars, and product monograph, write or call our PHYSICIAN INFORMATION SERVICE, 800-225-3226.

Hemorrhoid Case Study #1

Patient: 56-year-old business executive.

Symptoms: Profuse rectal bleeding.

Diagnosis: Patient had undergone a hemorrhoidectomy ten years previously. Complete colonoscopy revealed normal findings except for the recurrence of several symptomatic Grade 2 internal hemorrhoids.

Treatment: Patient's travel and work schedule precluded compliance with prescribed treatment of sitz baths and suppositories three times a day. A decision was made to use ULTROID.™ Two 6-minute treatments at 16 milliamps were administered over a one-week period. Patient tolerated maximum milliamperage well and reported no pain during or after treatment.

Result: Patient reported no disruption to his work schedule or lifestyle. Subsequent postprocedure follow-up indicated no recurrence of symptomatic bleeding.

What's New
In General Surgery

Current Laser Applications in General Surgery

JOHN A. DIXON, M.D.

From the University of Utah Department of Surgery Laser Institute, and the Laser Section, Salt Lake Veterans Administration Medical Center, Salt Lake City, Utah

THE POSSIBILITY of application of lasers as a surgical instrument has intrigued surgeons since the introduction of the first CO_2 medical lasers in 1967.[1] Laser surgery has been characterized by a great amount of basic research and clinical application in nearly every surgical specialty. Like most new instruments, procedures, or medications, laser surgery has gone through the usual cycle of abundant optimism and expansive claims, followed by complications and criticisms, followed by a gradual transition into realistic expectations and utilization. Fortunately, much of media hype and sensationalism regarding lasers in medicine has subsided and been replaced by careful evaluation and comparison with the established modalities and techniques. In some situations, such as endoscopic laser control of gastrointestinal (GI) bleeding, a reasonable number of prospective controlled randomized trials have been carried out. In many other instances, such as endoscopic laser pancreatic cystogastrostomy, however, the number of cases in which lasers have been employed are few and results almost anecdotal. Maturity in each specialty of each procedure must be evaluated.

A discussion of laser applications in general surgery must first approach the difficult task of defining general surgery. For the purpose of this paper, the American Board of Surgery description, which includes "general processes involving wound healing, hemostasis, neoplasia, and surgery of endocrine system, hernia, vascular system, gastrointestinal tract, abdominal organs and endoscopic principles and applications," will be utilized.[2] Lasers are employed relatively infrequently for limited indications by the traditional surgeon using incisional techniques. When one considers, however, the disease processes being treated by endoscopic laser techniques that would have formerly been managed by the general surgeon, a great impact on this specialty is evident.

Laser Fundamentals and Instrumentation

The principles necessary for the formation of the concept of lasers were noted as early as the 19th century with the presentation of Bohr's theory of optical resonators. In 1917 Einstein proposed the concept of stimulated emission of light.[3]

An extensive discussion of subsequent developments in laser physics is not consistent with this clinical review. In general, however, an atom, molecule, or ion in its resting energy state or ground state is excited to a higher energy state by the absorption of thermal, electric, or optical energy. After energy is absorbed, an atom, mole-

Submitted for publication: November 5, 1987.

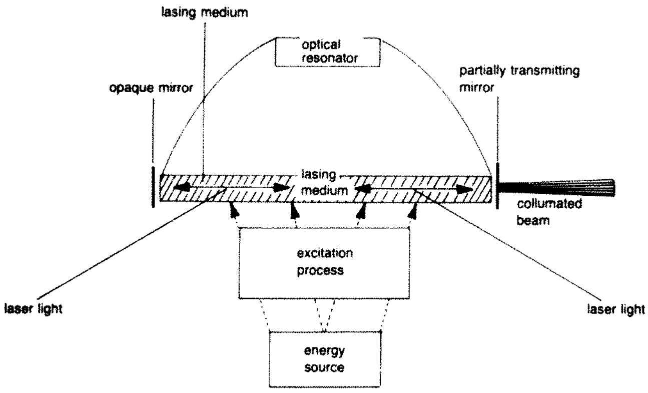

FIG. 1. Outline of laser operation. Energy source produces excitation process with excitation of lasing medium. Photons from lasing medium reflect off mirrors and are released through partially transmitting mirror (*right*).

cule, or ion spontaneously returns to a ground state and thereby liberates absorbed energy as a photon. The energy so created emerges as light that is coherent, of one wavelength, and in temporal and spatial phase (Fig. 1). This allows the beam to be focused, made divergent, or collimated (directed in parallel fashion, not focused or divergent). Such coherent light then may be focused on mirrors or flexible quartz rods (fiber) transmission.

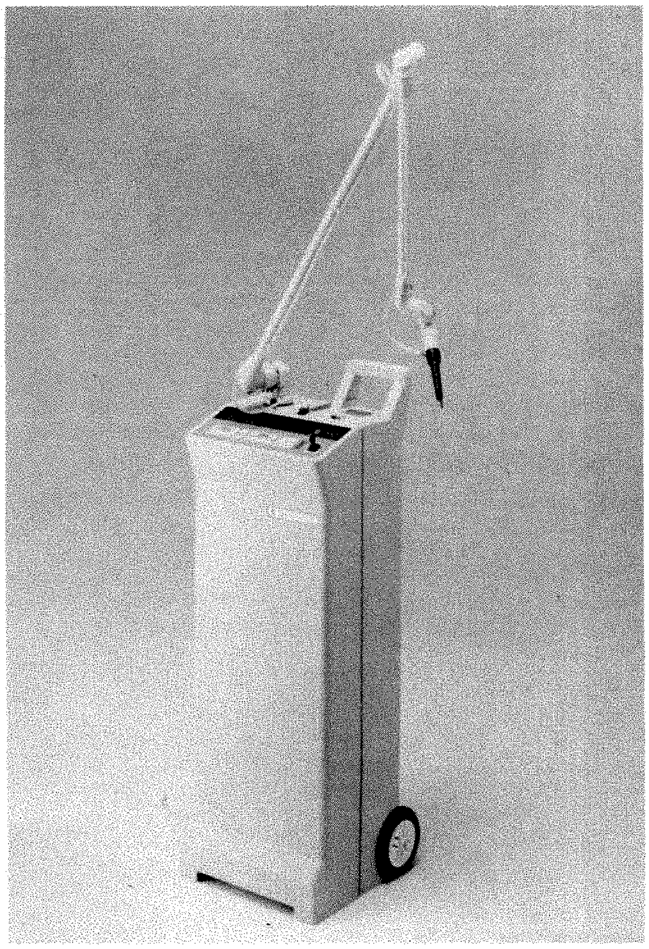

FIG. 2. Compact, portable 30 watt CO_2 laser with articulating arm for general surgical use (Sharplan Model 1020).

As laser light impinges upon tissue it may be reflected, absorbed, scattered, or transmitted.[4] The amount of absorption is determined by substances called chromophores. Two of the most common chromophores in tissue are hemoglobin and water.

Lasers in common use are the CO_2, argon, and neodymium YAG (Nd:YAG) lasers. Carbon dioxide laser energy (10.6 μm) is ideal for cutting and vaporization because it is heavily absorbed by water.[5] Unfortunately, CO_2 energy transmission requires a series of mirrors and an articulating arm for transmission. Although digital control of handpieces and articulating arms is fairly good, this method is still awkward in abdominal and other applications. Because of absorption by water, thermal injury from a given amount of energy from this laser is relatively superficial, ranging from 50 to 100 μm in depth. Small portable laser devices are available (Fig. 2).

Argon laser light (458–515 nm) is very heavily absorbed by hemoglobin and is especially useful in nonbleeding vascular lesions when precision and minimal depth of penetration (about 1 mm) are required.[6] Although heavily absorbed by blood, argon laser energy can be transmitted readily through water, gastric fluid, urine, *etc.*

The Nd:YAG laser (1.06 μm) has less specific absorption by water and hemoglobin than the preceding two lasers.[7] This results in a depth of thermal injury of approximately 3 mm in most tissues, which is useful for coagulation of large volumes of tissue such as in palliative coagulation of esophageal and colonic carcinomas.

While most laser applications are made using a noncontact technique, there has been recent introduction of a variety of sapphire or ceramic contact tips for handheld or endoscopic use, which allow for application of pressure to bleeding vessels or highly focused laser energy on the tip of a laser scalpel to minimize diffusion and laser tissue injury (Fig. 3).[8]

Unlike many surgical devices, the laser may harm surgeons and operating personnel as well as patients.[9] Goggles or appropriate eye wear with filters capable of protecting against the wavelength in use must be worn at all times. Access to the operating suite must be controlled so that individuals without appropriate eye wear do not enter. Surgical instruments in the field must be of a nonreflective type. Operating room drapes must be moistened or inflammable. Endotracheal tubes must be either metal or wrapped with reflective tape to prevent ignition or melting.[10]

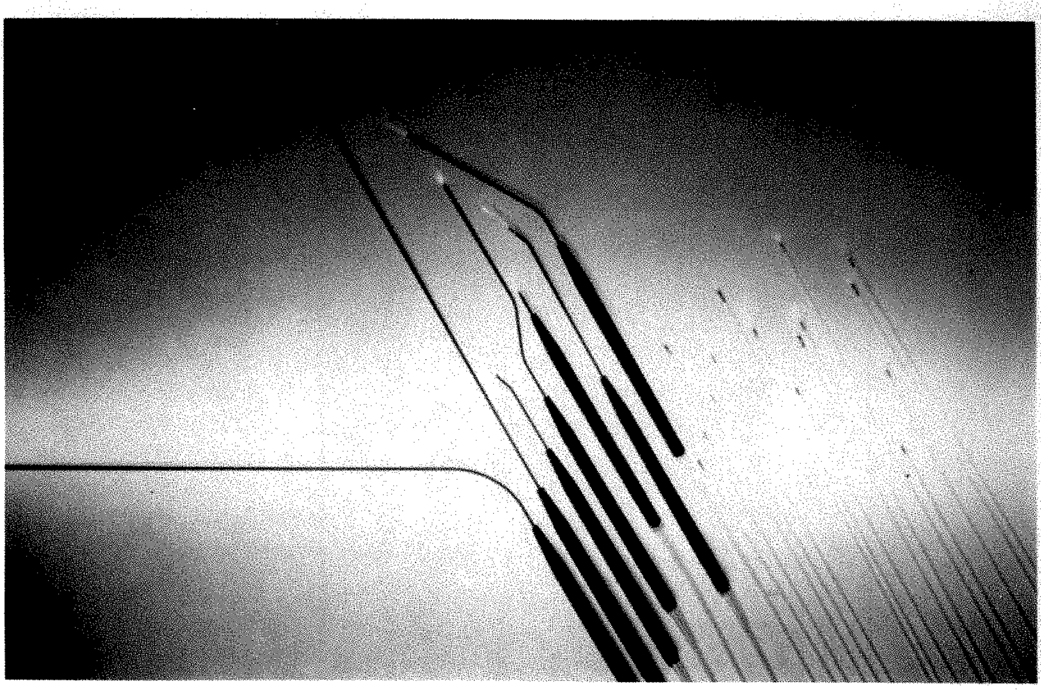

FIG. 3. Variety of handheld (left and endoscopic right) sapphire tips for operative and endoscopic use (Surgical Laser Technologies).

Where lasers are to be widely utilized, it is necessary to have a central organization to provide for laser safety, scheduling, maintenance of laser devices, fiber preparation, credentialing of users, and in-service training of personnel. The complexity of this organization depends upon the number of lasers and frequency of usage. Such units are usually managed by a part-time director and laser safety officer, with an advisory committee made up of representatives of the specialties using the laser. Shared use of lasers can greatly reduce cost per patient.[11]

Basic Surgical Processes

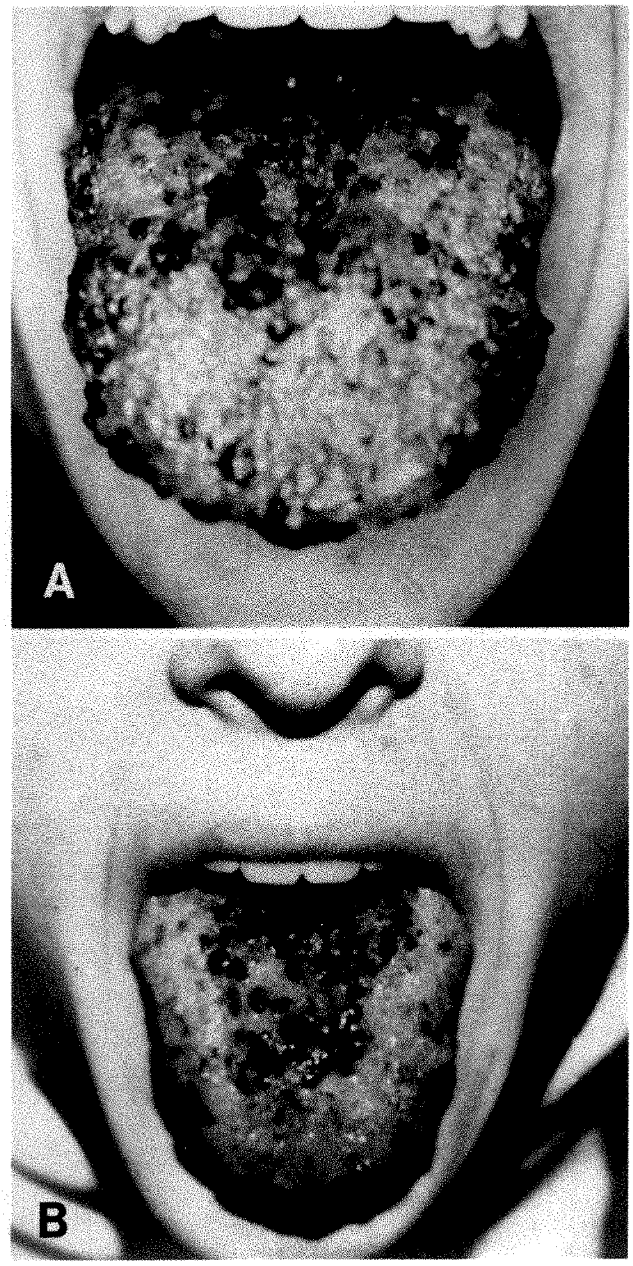
As compared with the scalpel, laser cutaneous incisions demonstrate delayed epithelial migration, prolonged period of wound phagocytosis, and decreased tensile strength up to 7–28 days.[12] This is probably due to thermal damage from the laser. After that period wound healing as measured by tensile strength is similar with both laser and scalpel.[13] The clinical significance of these findings is obscure at this time. The most practical recommendation is that cutaneous sutures remain in for an additional 3–5 days in laser incisions to allow for the more prolonged healing processes described.

Several authors suggested that low energy "soft or cold" lasers may result in biostimulation with acceleration of the rate of healing of wounds.[14,15] Mester and Mester reported that phagocytosis by leukocytes increases in response to helium-neon or argon laser at 0.5 J/cm^2 and that an accelerated growth of fur on mice occurs in response to exposure to low energy radiation.[16] Kana irradiated skin wounds in rats with the helium-neon laser at 45 mw/cm^2 and reported a statistically significant stimulating effect on collagen synthesis in the wound as measured by rate of wound healing and hydroxyproline content.[17]

The very considerable experience of the Mester's in patients with cold laser stimulation of healing in indolent leg and decubitus ulcers is interesting and merits continued observation. The application of argon laser at 4 J/cm^2 twice a week in over 1300 patients resulted in healing in a variety of lesions that were resistant to conventional treatment.[18] However, the problem of documentation in this area is great and statistical analysis difficult. So little is known of this type of laser/tissue interaction that one should be careful concerning premature acceptance or dismissal of biostimulatory effects. As is the case with many therapeutic agents, dosage may be critical with one energy dose being stimulatory and a slightly different one of the same wavelength being inhibitory or destructive.

Laser energy, especially at wavelengths in the hemoglobin absorption peaks, ruptures red blood cells, damages platelets, and activates clotting cascades with thrombus formation.[19] Endothelial damage, protein denaturation, shrinkage, and perivascular edema likewise contribute to vessel closure. Each laser, however, has limitations as to the size of vessels that can be controlled. The defocused CO_2 laser can coagulate vessels up to approximately 0.5 mm; the argon laser up to 1 mm; and the Nd:YAG laser up to 3 mm.[20]

Despite numerous anecdotal clinical references to decreased blood loss with laser surgery, statistical evidence is not readily at hand. One controlled study on burn excision in pigs showed a significant reduction in blood



FIGS. 4A and B. *A*. Lymphangioma of tongue with recurrent bleeding. *B*. Three months following Nd:YAG laser therapy. Marginal 3 cm of tongue treated by spot technique. Central portion of tongue untreated.

loss when experimental burns were excised with the argon laser as compared with electrosurgery.[21] There are several reports of reduced blood loss in experimental and clinical hepatic resections utilizing the CO_2 or Nd:YAG laser.[22,23] On the other hand, a controlled study using the Nd:YAG laser in canine experiments failed to show a statistically significant reduction on blood loss when the laser was employed for hepatic surgery in a noncontact fashion.[24] Decreased blood loss was recorded in experimental partial splenectomy[25] and clinically in mastectomy.[26]

One important area of laser hemostasis involves emergency surgery in patients with hemophilia, thrombocytopenia, or other coagulopathies. Due to vessel closure by thermal factors, it is reported that bleeding can be controlled by lasers during urgent procedures in such individuals. Kiefhaber stated that a platelet count of 25,000 is the minimum necessary for laser hemostasis in the GI tract.[105] A recent study involving the use of the CO_2 laser in surgery in hemophiliac patients undergoing synovectomy of the knee noted a significant reduction in blood loss, necessity for blood factors, time of operation, and duration of hospitalization compared with conventional techniques.[27]

Early reports suggested that infection in laser wounds would be reduced due to high temperatures created with bacterial "sterilization."[28] Shultz et al. studied the effect of Nd:YAG laser energy on three bacterial strains: *Staphylococcus aureus, Escherichia coli,* and *Pseudomonas aeruginosa.*[29] Energy fluence of 1667–3333 J/cm^2 resulted in a 2–8 log decline in a number of viable bacterial colonies. *P. aeruginosa* was the most sensitive to the Nd:YAG laser.[29] A study employing the CO_2 laser with *E. coli* and *S. aureus* also showed a dramatic reduction of bacteria.[30] It appears that lasers may reduce bacterial colonization at the time of incision, but experimental laser wounds subsequently contaminated have a higher incidence of infection.[31] Sterilization by laser is unlikely, but reduction of bacteria in necrotic infected wounds is probable.

It is evident from experimental and clinical studies that tumors can be coagulated or vaporized using the thermal effects of the laser.[32] Controlled studies in the bladder[33] and gastric cancer are in progress to determine comparative efficacy of endoscopic laser and conventional treatment. Sealing of lymphatics by lasers in tumor surgery is still uncertain. Frishman et al. reported a reduction in pulmonary metastasis when the CO_2 laser was used to excise experimental subcutaneous fibrosarcomas.[34] Oosterhuis et al., in a careful study of Cloudman melanoma cell dispersion, reported that CO_2 laser was "no worse than the conventional scalpel" in dissemination of cells from the incised tumor.[35] In a recent experimental study comparing the effect of circumferential Nd:YAG laser and electrocautery applications around the dome of the urinary bladder in restricting lymphatic migration of carbon particles, there was a statistically significant lesser degree of particulate migration through the laser barrier as compared with electrocautery.[36] Lanzafame et al. found that wound recurrence of experimental tumors in Fisher rats was significantly reduced by CO_2 laser excision.[37] Viable tumor cells were not found in the smoke plume during tumor vaporization with the CO_2 or Nd:YAG laser.[38,39]

Possible carcinogenic effects of lasers must be consid-

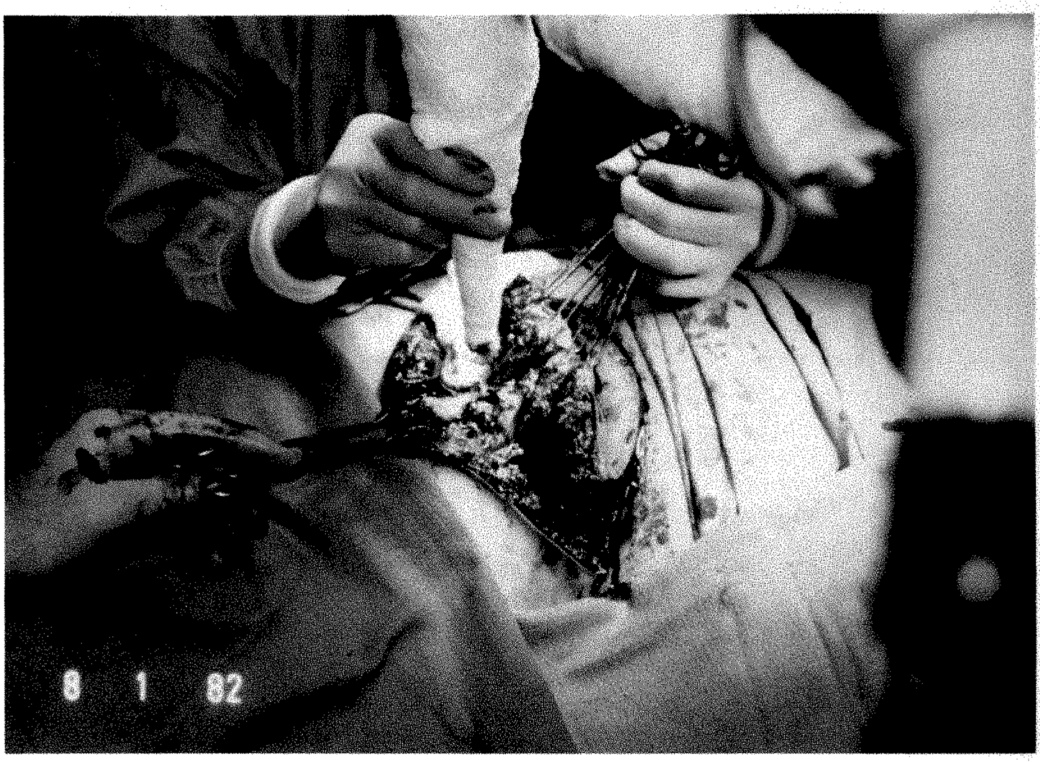


FIG. 5. Vascular infiltrative neurofibroma of abdominal wall being excised with CO_2 laser (center, gauzed-wrapped). Two previous attempts with conventional excisional methods failed due to severe hemorrhage.

ered. Goldman observed a group of human volunteers subjected to repeated low power argon cutaneous applications; no tumor formation was noted.[40] Apfelberg et al. carried out an *in vitro* study of fibroblast cultures irradiated with argon laser; no mutagenic effects were observed.[41]

Clinical Applications

Current clinical applications of lasers in general surgery are presented in two sections. The first section deals with conventional incisional surgical access laser techniques. The second section deals with the vast and rapidly growing endoscopic access laser surgical techniques, or minimally invasive endoscopic gastrointestinal laser surgery.

Coagulation and Excisions of Masses and Tumors

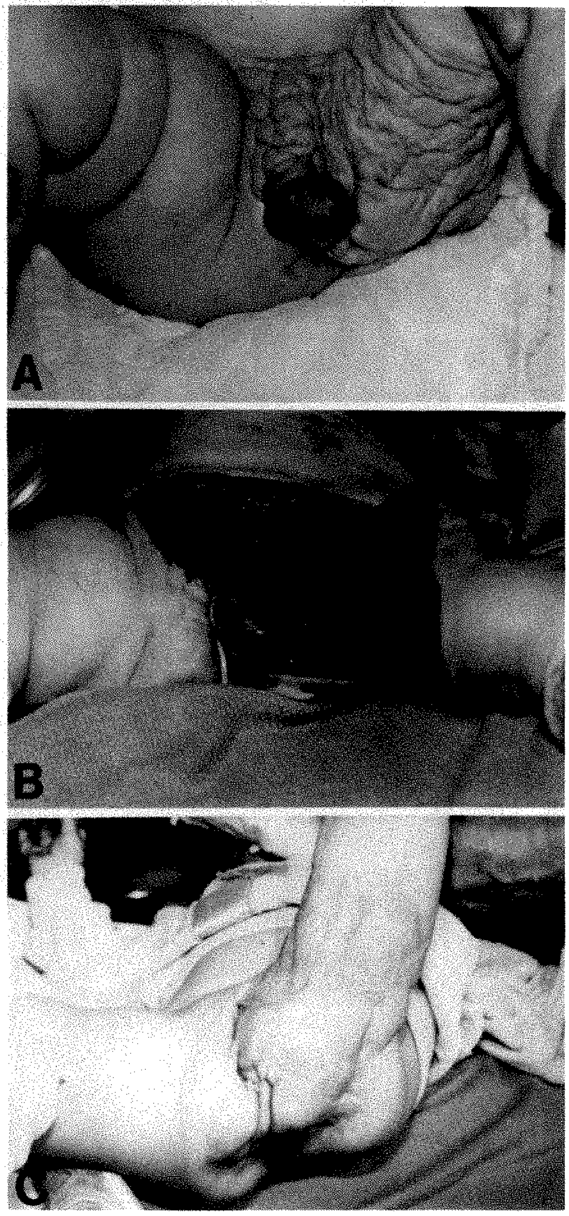
With its rich vascular supply, the tongue has been a difficult organ for the general surgeon to incise using standard techniques. With masses that are rather small and localized, excision with the CO_2 laser may be accomplished quickly and with minimal blood loss.[42] Due to rapid reparative processes of the tongue, thermal injury of laser does not result in significant delay in healing.

A conservative palliative application for control of vascular lesions of the tongue with lasers is being utilized. Argon and Nd:YAG lasers have been used effectively in a palliative fashion to reduce bleeding and size of such lesions without loss of functional tongue mass in 13 patients. A spot coagulation technique without cutting or vaporization is employed (Fig. 4). This has resulted in reduction of bleeding and lesion size for periods of up to 3 years. Retreatment has been required as symptoms recur.[43]

The CO_2 laser has been used effectively to treat leukoplakia and lesions of the oral mucosa. The unique superficial vaporization of this laser allows for a precise microsurgical removal of the dysplastic tissue. If the lesions are extensive, resultant ulcerations may require several weeks to heal completely and be quite uncomfortable for the patient. The recurrence rate, however, is much less than that with other techniques.[44]

Excision of vascular lesions of the scalp may likewise be facilitated with use of the CO_2 laser. Smaller vessels in the skin may be readily photocoagulated and larger vessels exposed. These vessels can be controlled by clips, ligature, or electrocoagulation. The bed in such excisions readily accepts a graft without delay in graft take or healing.[45] Similar vascular lesions of the trunk, abdominal wall, and extremities may be excised with reduced blood loss (Figs. 5 and 6).

A number of reports indicate facilitation of excision of head and neck tumors with the CO_2 laser, indicating better exposure, less blood loss, and decreased operating time.[46] A more specific application was outlined by White and Adkins for excision and vaporization of lym-



FIGS. 6A–C. *A.* Lymphangiosarcoma in 3-week-old female infant. *B.* Immediately following excision with CO_2 laser; 120 mL blood loss. *C.* Two years following skin graft, no recurrence. External genitalia preserved.

phangiomas of the head and neck in children.[47] Multiple thin-walled small extensions of the tumor that were difficult to excise were ablated by a handheld CO_2 laser technique.[47]

Breast

Considerable experimental and clinical study has been made of the carbon dioxide laser in treatment of carcinoma of the breast. Lanzafame et al. compared local tumor recurrence following scalpel, electrocautery, and laser excision of R3230AC mammary tumors in rats.[48] A statistically significant ($p < 0.05$) reduction in recurrence was noted with laser excision as compared with scalpel excision.[48]

In a controlled trial involving 209 patients, Ansanelli compared CO_2 laser excision and scalpel excision of breast malignancies.[49] Transfusions required, postoperative wound drainage, and hospital stay were all less for inpatients where CO_2 excision was performed.[49]

Recurrent breast cancer in the thoracic wall with necrosis and ulceration is a difficult surgical problem. Hira et al. utilized CO_2 laser and vaporization for excision of such tumors with reduction in blood loss and local infection. In a 2-year follow-up, however, no difference in rate of local recurrence between the control or treated groups was noted.[50]

Abdomen

Stomach

The Nd:YAG laser is frequently used in Russia for excision of gastric lesions with a report of decreased infection and blood loss. Special devices have been constructed to allow uniform circumferential transsection of stomach and intestine. It is suggested that there is better sterilization, less tissue turn in, and reduced anastomotic complications using this technique.[51] Hira and Moore employed similar contact techniques in 30 intraabdominal anastomotic procedures and stated that the laser did not damage intestinal margins as much as other methods, and was especially useful in excising inflammed vascular neoplastic tissue.[52]

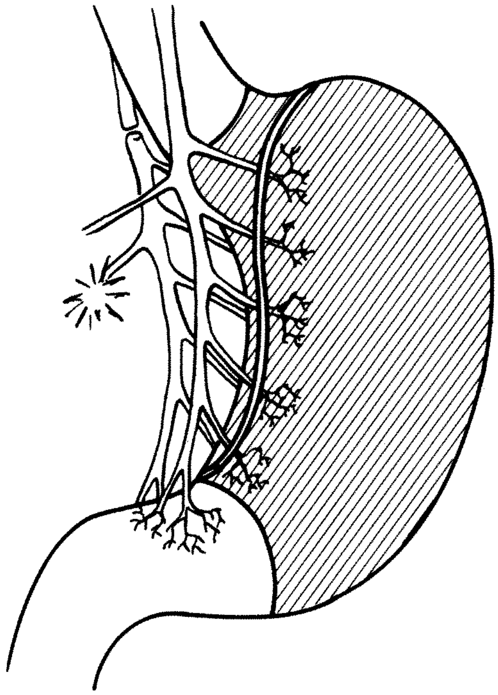


FIG. 7. Experimental laser vagotomy. Posterior truncal vagotomy followed by division of branches of anterior vagus along lesser curvature to nerve of Latarjet with either adjacent spot application or continuous sweep application of argon laser.

An unusual experimental gastric application has been suggested by Hunter et al. utilizing the argon laser plus vagotomy in dogs.[53] In this procedure, the posterior vagal trunk is divided. Following this, a laser myotomy is performed applying the argon laser along the anterior curvature from gastroesophageal junction to the nerve of Latarjet coagulating serosa and muscularis leaving muscosa intact. This procedure is designed to interrupt both the extramural and intramural branches of the left vagus nerve. Secretory studies indicating marked reduction in secretion are encouraging (Fig. 7).[53]

Pancreas

Excision of the pancreas has been performed using Nd:YAG laser in both experimental and clinical situations.[54] Donna utilized the Nd:YAG laser in order to preserve the duodenum with its blood supply in canine surgical procedures.[55] A statistically significant reduction in operating time and blood loss was reported.

Liver

The liver was early suggested as a site for laser applications for hemostasis or sublobar excisions.[56] Laboratory studies indicate that it is feasible to excise portions of the liver with CO_2 or Nd:YAG laser. Schroder et al. employed contact tip Nd:YAG excision combined with a flexible plastic strapper for canine liver resections with reduction in operating time and blood loss.[57]

It appears, however, that the present lasers may be most useful for hemostasis involving large oozing surfaces of the liver due to trauma. Standard surgical techniques will likely continue to be utilized in elective lobar resections to control major vascular and biliary structures. Sublobar resections and vaporization of scattered hepatic metastases, especially in tumors of endocrine origin, may be facilitated by the use of lasers.

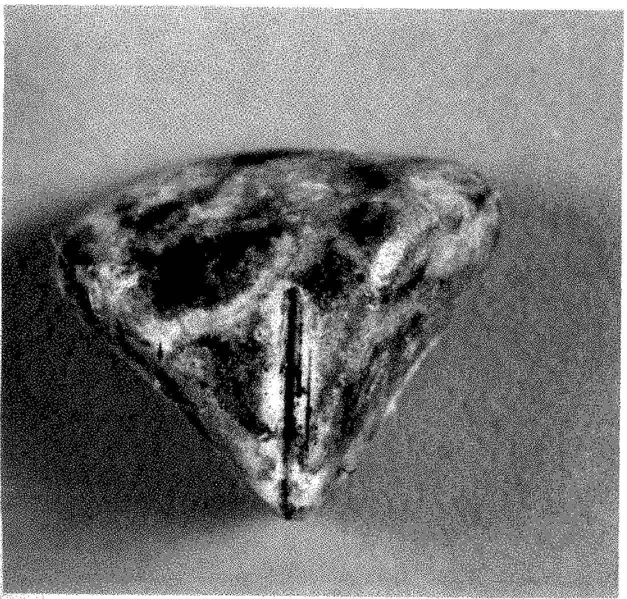

FIG. 8. Mixed calcium cholesterol pigment stone. Central incision made with free electron laser at 2.9 μm wavelength. Small incision on stone to right of center 20 μm width. No evidence of thermal damage.

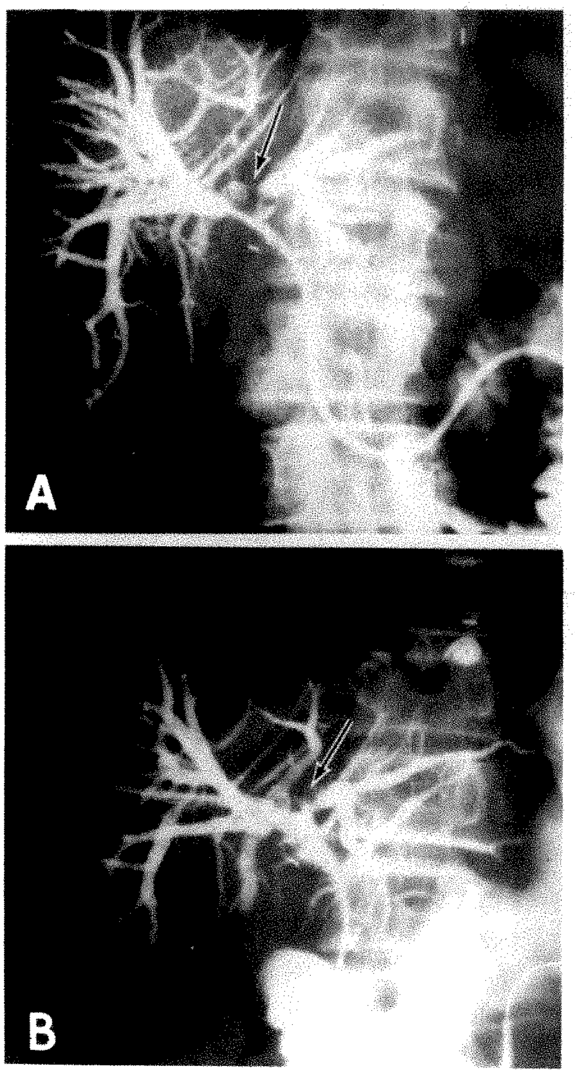

FIGS. 9A and B. *A*. Cholangiogram of patient with Klatskin tumor. A percutaneous tube is draining the right hepatic duct system. The left remains obstructed (arrow). *B*. The same patient following endoscopic laser treatment of tumor required to control hemorrhage. The left hepatic duct system is no longer obstructed (arrow).

Biliary

Biliary calculi can be fragmented and removed using the Nd:YAG laser. The laser is guided by endoscopic means using a transampullary, percutaneous transhepatic, or tube tract approach.[58] Pigmented and mixed stones are readily reduced to smaller pieces. Pure cholesterol stones or heavily calcified stones are more difficult to reduce. Fragmentation is achieved by placing a fiber in contact with the stone and applying repeated brief impulses. Stones may then be removed by catheter or by grasping forceps. This technique may be especially

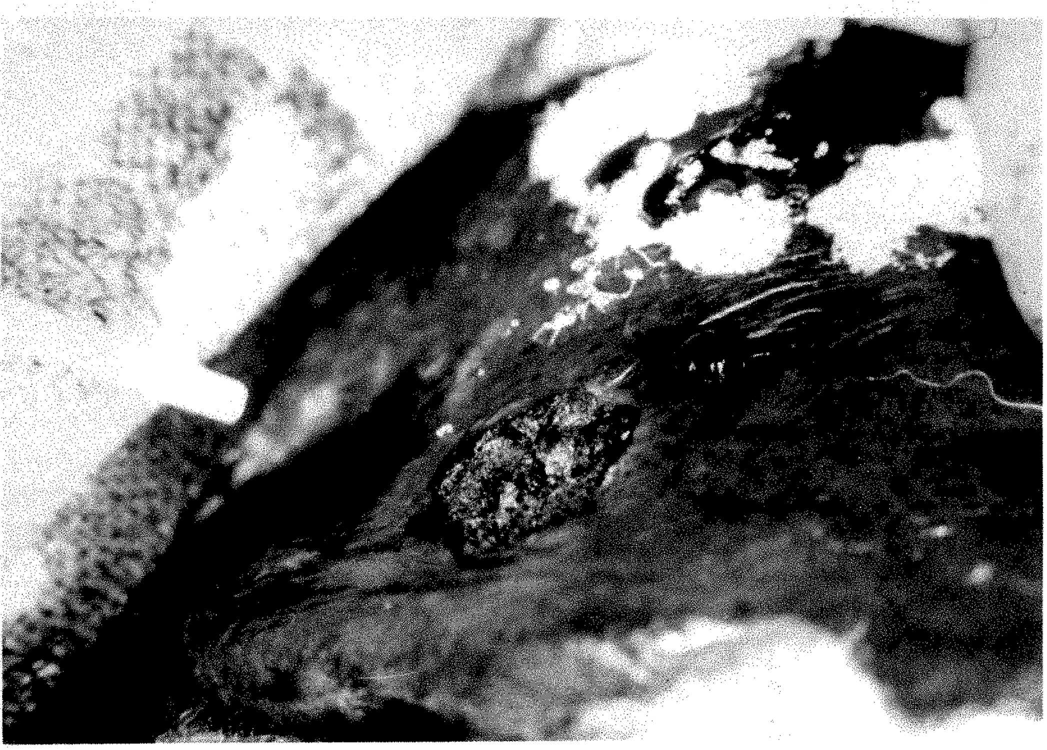

FIG. 10. Superficial capsular injury of spleen. Bleeding through microfibrillar collagen (*top*). Control of bleeding with multiple application of Nd:YAG laser, fiber at left (*bottom*).

useful in retained intrahepatic stones that cannot be removed by conventional techniques.[59]

A major problem with gallstone fragmentation with the Nd:YAG laser is the generation of heat that can damage biliary mucosa. The recent introduction of the flash lamp pumped dye (400–750 nm) laser for fragmentation of urinary calculi suggests this same technology may be applicable to biliary calculi.[60] The exact mechanism of stone fragmentation by this technique is not fully defined but may result from plasma formation and with photomechanical disruption. Dayton and Dixon measured *in vitro* thermal effects of gallstone fragmentation with Nd:YAG, copper vapor, and flash lamp pumped dye lasers.[61] Significant peripheral temperature elevations were noted during fragmentation with Nd:YAG and copper vapor but not with flash lamp pumped dye laser.[61] The free electron laser was utilized to photoablate gallstones by Dixon et al.[62] This high energy pulsed device allows precise incision and reduction in size of stone with minimal thermal effects (Fig. 8). These devices, possibly combined with ultrasonic fragmentation, suggest a future role for laser applications especially for intrahepatic, retained common duct calculi, and possibly even gallbladder stones.

A unique hepatobiliary endoscopic application of the laser involved percutaneous transhepatic insertion of an endoscope into dilated biliary radical above bleeding intrahepatic bile duct tumors. Utilizing the Nd:YAG laser fiber through a pediatric bronchoscope, bleeding from a Klatzkin tumor was controlled and symptomatic relief from obstruction provided (Fig. 9).[63] The Nd:YAG laser has also been used for endoscopic papillotomy where conventional techniques have failed.

Spleen

The Nd:YAG laser has been found to be effective in controlling experimental superficial splenic capsular bleeding (Fig. 10). Larger central vessels cannot be controlled with the laser. A technique has been described for segmental or partial splenectomy involving ligature of selected hilar vessels and Nd:YAG vaporization of splenic capsule, superficial sinusoidal tissue, and smaller peripheral vessels. Coagulated material is aspirated. As the hilum is approached, vessels larger than 1 mm are skeletonized, clipped, or suture-ligated. (Fig. 11).[64]

Anal and Regional

Laser hemorrhoidectomy is reported with increasing frequency but still remains controversial. The CO_2 laser is used in some techniques in conjunction with standard surgical ligation and excision. The laser is reported to be effective in elevating mucosal flaps with preservation of anoderm and reduction in pain.[65,66]

Sankar and Joffe devised a new technique of hemorrhoidectomy utilizing a Nd:YAG with contact tips as an excisional method.[67] A limited clinical trial indicated less blood loss, pain, urinary retention, and fewer healing complications as compared with conventional techniques.[67]

The removal of condylomata of the perianal region may be accomplished with CO_2, argon, or Nd:YAG lasers.[68] With all wavelengths, it is essential to remove all epidermis for at least 1 cm surrounding any active lesion since virus has been found in prickle cells for at least that distance. If the brush technique described by Baggish is not employed, the recurrence rate is much higher.[69]

Since live virus may be disseminated in the air during condylomata vaporization, gloves, masks, gowns, and other precautions are essential.[70]

Pilonidal Cystectomy

CO_2 excision of pilonidal cyst has been reported. The hemostatic and bacteriocidal effects of the laser are utilized in tracing out and excising, or vaporizing, the numerous tracts of this troublesome lesion.[71]

Decubitus Ulcer

Excision of decubitus ulcers with the CO_2 laser has been described in reports of treatment of several thousand patients.[72] The ability of the laser to vaporize infected tissue is used, which allowed earlier grafting of the exposed site.

A controlled trial of laser *versus* conventional ulcer excision involving 66 patients was conducted by Juri et al.[73] Statistically significant differences in favor of the laser-treated groups were noted in operative blood loss, infection rate, and recovery rate. The sum of these factors resulted in a mean of 23 fewer hospital days per excisional procedure in laser-treated patients as compared with control patients (Fig. 12).[73]

Infected Wounds

Primary closure of phlegmons, abscesses, and carbuncle following total excision with CO_2 laser was reported

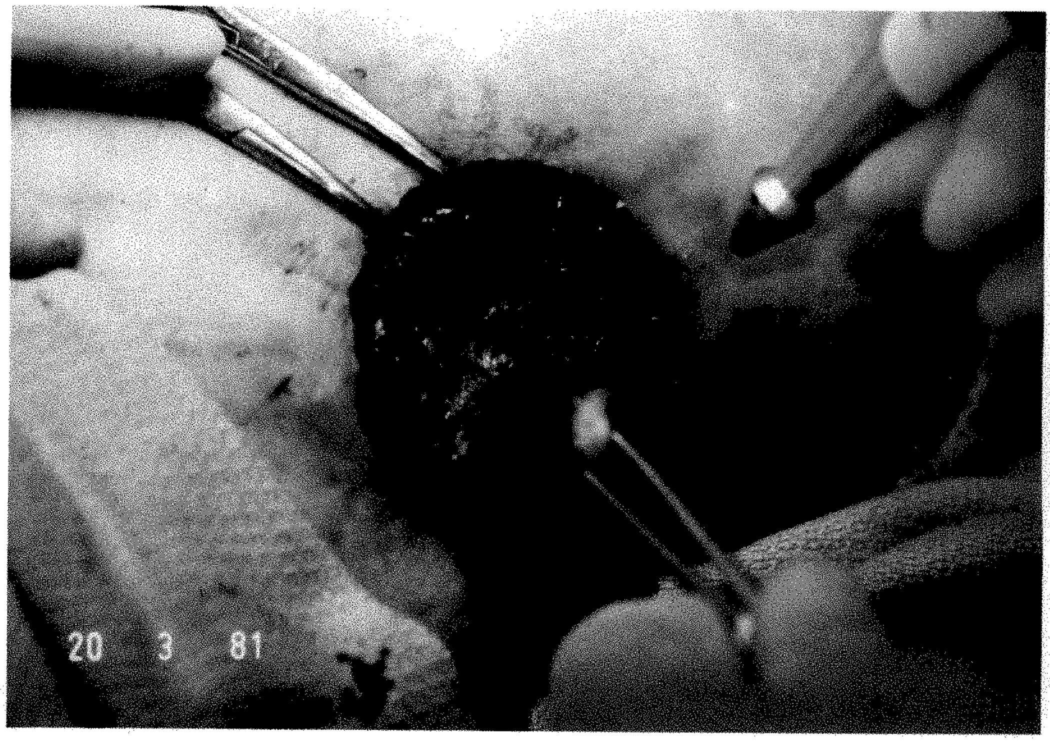

FIG. 12. Excision of decubitus ulcer with CO_2 laser. Necrotic base has been vaporized followed by circumferential excision of entire ulcer and bed (CO_2 laser handpiece, *upper right*).

Postsurgical anastomotic bleeding

by Chegin et al.[74] Tube drainage was frequently utilized; of 247 patients so managed, 233 did not require further incision or drainage.[74]

Endoscopic Gastrointestinal Laser Surgery

Remarkable advances in the endoscopic approach to intraluminal (and selected extraluminal) GI lesions have been made. Newer endoscopic devices provide excellent visualization of mucosal or submucosal lesions with ample operative channels for introduction of laser fibers or a variety of electrosurgical or heater probes. A partial list of endoscopic GI laser surgical procedures employed for treatment of general surgical disease processes appears in Table 1. Space limitations allow only briefest mention of representative applications in acute GI hemorrhage, vascular malformations, small benign mucosal lesions, GI malignancy, cysts, and stenoses.

Gastrointestinal Bleeding

A summary is available of nine prospective controlled randomized studies of endoscopic laser treatment of patients with acute upper GI hemorrhage (mostly peptic ulcers).[75] Three of the studies failed to show significant differences in long-term hemostasis or requirements for surgery or survival, although initial hemostasis was achieved in approximately 90% of laser-treated patients. A study by Rutgeerts et al.,[76] which included the largest number of patients, however, showed a statistically significant decrease in rebleeding rate, necessity for urgent surgery, and reduction of mortality rate in laser-treated patients. Laser therapy for active GI hemorrhage appears to be beneficial only in patients with actively bleeding peptic ulcer disease or with nonbleeding visible vessels in an ulcer crater. Lesions such as diffuse gastritis and those inaccessible endoscopically are not suitable for laser therapy.

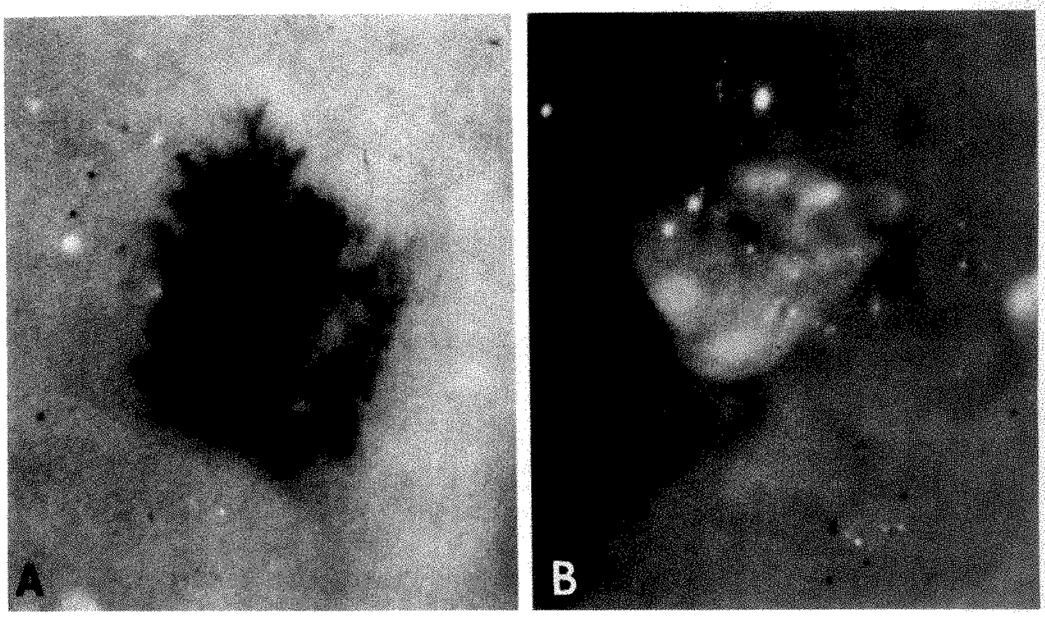
One of the greatest indirect contributions of the laser for endoscopic therapy has been the requirement for precise early identification of the bleeding lesion. This has resulted in new visual management criteria based upon the presence or absence of spurting lesions, visible vessels, or stigmata of recent hemorrhage.[77] Massively bleeding arterial lesions are recognized early and referred for surgery without further delay. Endoscopic laser conversion from bleeding to stabilized patients, even for a brief period of time, may assist the surgeon in management of these difficult problems.

Vascular Malformations

These lesions are particularly suited to laser therapy since they are frequently limited to the mucosa or submucosa and heavily absorb light in the argon range (Fig. 13). The combined experience at the Universities of Utah and Lille now includes 80 patients with upper GI, 26 with colonic, and nine patients with upper and lower vascular lesions. Twenty had Osler-Weber-Rendu (OWR) syndrome. The overall results in these patients were similar to other reports with over 95% success in controlling blood loss in patients with sporadic vascular malformations and reduction in frequency of bleeding in patients with the OWR syndrome.[78] No perforations or major complications occurred. Rutgeerts et al. reported the treatment of 482 GI vascular lesions in 59 patients with Nd:YAG laser.[79] Overall results were good with only 17 patients rebleeding.[79] Buchi followed 44 patients for up to 3 years following laser treatment of vascular malformations and found a statistically significant reduction in frequency of bleeding, transfusion rates, and requirement for surgery.[80] The collective experience of various centers indicates that laser treatment of GI vascular malformations is safe and effectively terminates or markedly decreases frequency of bleeding.

Small Multiple Benign Mucosal Lesions

Dixon et al. studied endoscopic argon laser treatment in 34 patients with Gardner's syndrome with multiple polyps in residual rectum following subtotal abdominal colectomy.[81] Over 1100 polyps were removed without



FIGS. 13A and B. *A*. A 5-cm diameter superficial hemangioma of lesser curvature of the stomach with recurrent bleeding. *B*. Immediately following argon laser photocoagulation of hemangioma. No recurrence after 3 years follow-up.

complication (Fig. 14). A similar experience was noted by Brunetaud et al. at the University of Lille.[78] Other lesions successfully treated include gastric polyps, endometriosis coli, and localized lesion in Barretts' esophagus. The laser should not be used to remove pedunculated polyps since there is usually a central vessel that is difficult to control without the constrictive effects possible with electrocautery snares.

Villous Adenoma

The management of villous adenoma is more controversial. Lambert and Sabben reported complete laser destruction of 35 of 39 villous adenomas, with reduction of size of lesion in the remainder; four perforations were noted, but two did not require treatment.[82] Brunetaud recently reported treatment of 109 villous adenomas in this fashion; 19% had local recurrence, but all were successfully ablated with repeated laser treatment.[83] Five patients with invasive carcinoma were discovered in the course of treatment and referred for surgery.[83]

Gastrointestinal Malignancy

Palliative therapy of GI malignancy is one of the more appealing applications of endoscopic laser surgery. Neoplasms of the esophagus, stomach, duodenum, hepatobiliary tract, colon, and rectum have been managed in this fashion for control of bleeding, relief of obstruction, management of secretions, or to allow oral nutrition (Fig. 15).[84] Applications have been made in lesions that are incurable by surgical resection, recurrent lesions, in patients who cannot withstand a surgical procedure, or in preparation of a patient for surgery. Laser procedures have the advantages that they can be carried out with minimal or no sedation and generally on an outpatient basis, with potential reduction in complications, medical costs, and hospital stay.

Fleisher and Sivak[85] treated 68 patients with esophageal cancer with the Nd:YAG laser who were not candidates for surgery or radiation therapy, with relief of dysphagia in 92% and clinical improvement lasting 3–6 months. Five patients (12%) developed tracheoesopha-

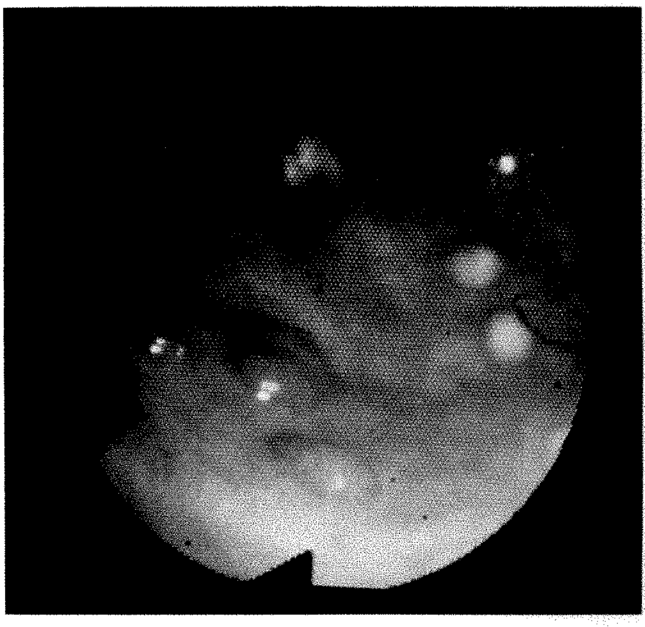


FIG. 14. Multiple polyposis of colon (Gardner's syndrome). Untreated polyps (*below*). White coagulated polyps treated with argon laser (*above*).

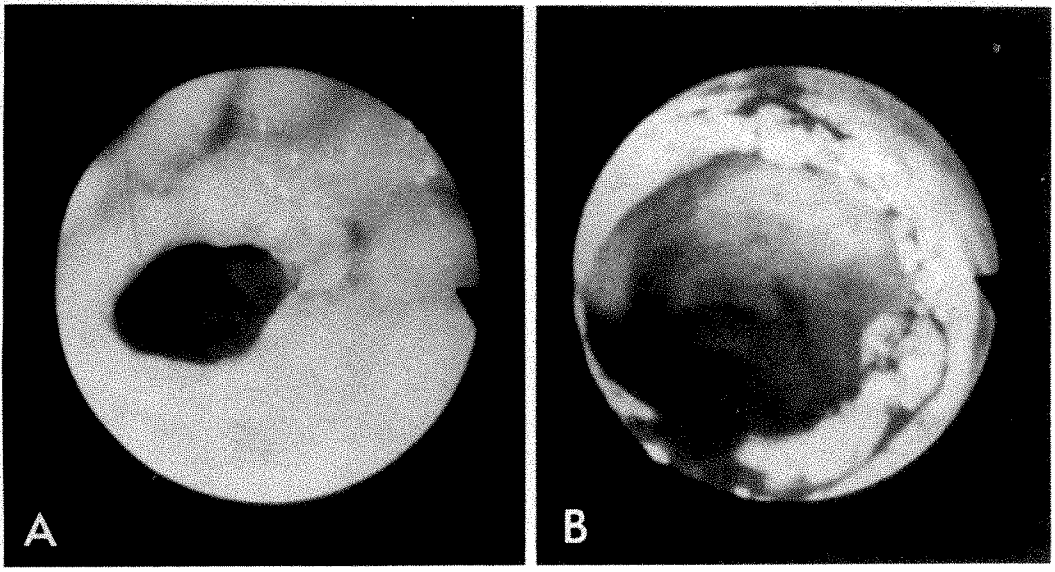
LIBRARY



FIGS. 15A and B. *A.* Stenosis of low rectal anastomosis with recurrent malignancy at suture line in patient with distal metastases. *B.* Immediately following Nd:YAG incision of stenosis and vaporization of tumor. Patient died 13 months later without recurrence of stenosis or local tumor.

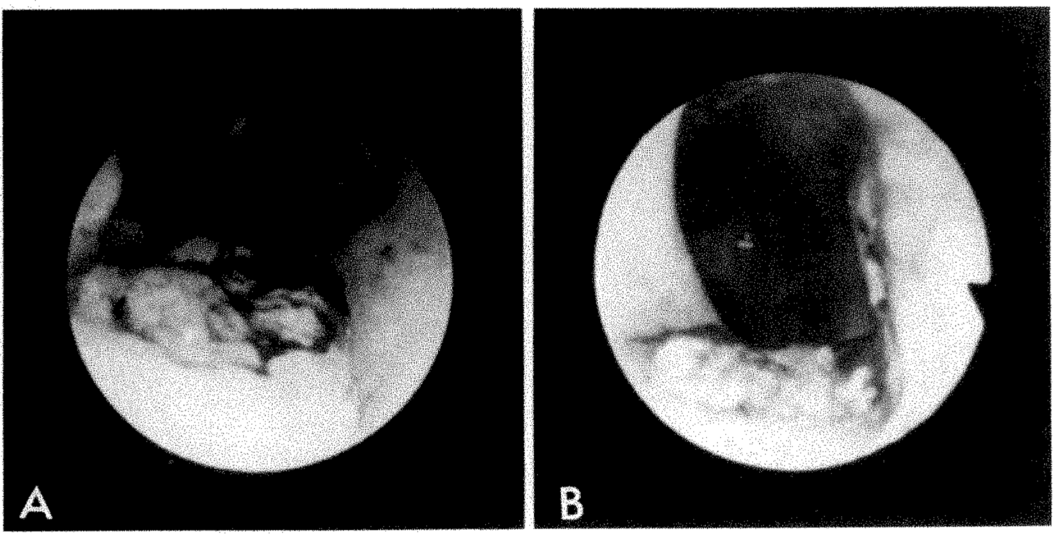
geal fistulae or perforation. Two of these were clearly laser-related, but the other three occurred up to 6 months after laser treatment. Patients managed in this fashion required retreatment as progression of the growth occurs.[85] As would be expected, no increased length of survival was noted.

Gastric and distal esophageal malignancy may be managed by endoscopic laser therapy with similar results. Thirty-four patients were treated at the University of Utah Laser Institute; 91% of patients were relieved of gastric or distal esophageal obstruction and 2% developed fistulae.[78]

In a cooperative study 118 patients were treated for surgical preparation or palliation of colorectal malignancies at the University of Utah and the University of Lille. Control of bleeding or relief of obstruction with the Nd:YAG laser was possible in all patients (Fig. 16). An average of three initial treatment sessions was required. Few complications were encountered.[78] Again, retreatment was necessary as tumor growth progressed.

Endoscopic Incisional

Increasing experience with endoscopic surgery has resulted in unique applications involving endoscopic incisional methods. This has been facilitated by the development of contact tips for laser fibers, which allow for precise laser application to such lesions. Potential procedures of this type are limited only by visualization of the lesion and endoscopic skills of the surgeon. Delmotte et al. utilized the argon laser to drain pancreatic and biliary cysts internally.[86] Buchi et al. employed the Nd:YAG laser to drain two symptomatic expanding



FIGS. 16A and B. *A.* Cancer of rectum with acute bleeding. *B.* Immediately following Nd:YAG endoscopic photocoagulation with control of bleeding. Patient was then treated surgically on elective basis.

traumatic pancreatic pseudocysts in patients who could not undergo operative cystogastrostomy.[87] An area of the gastric wall overlying the pseudocyst was heavily photocoagulated, and subsequent slough created a large pseudocystogastrostomy. No recurrence of cysts was noted in a 3-year follow-up (Fig. 17).[87]

A number of reports have described the use of lasers for successful incision and enlargement of postoperative stenosis of the esophagus and colon.[88] Peptic strictures, congenital rings, and postoperative webs have likewise been incised and dilated (Fig. 18).[89] Innovative incisional applications are in the early investigative phase but promise to greatly influence the practice of GI surgery.

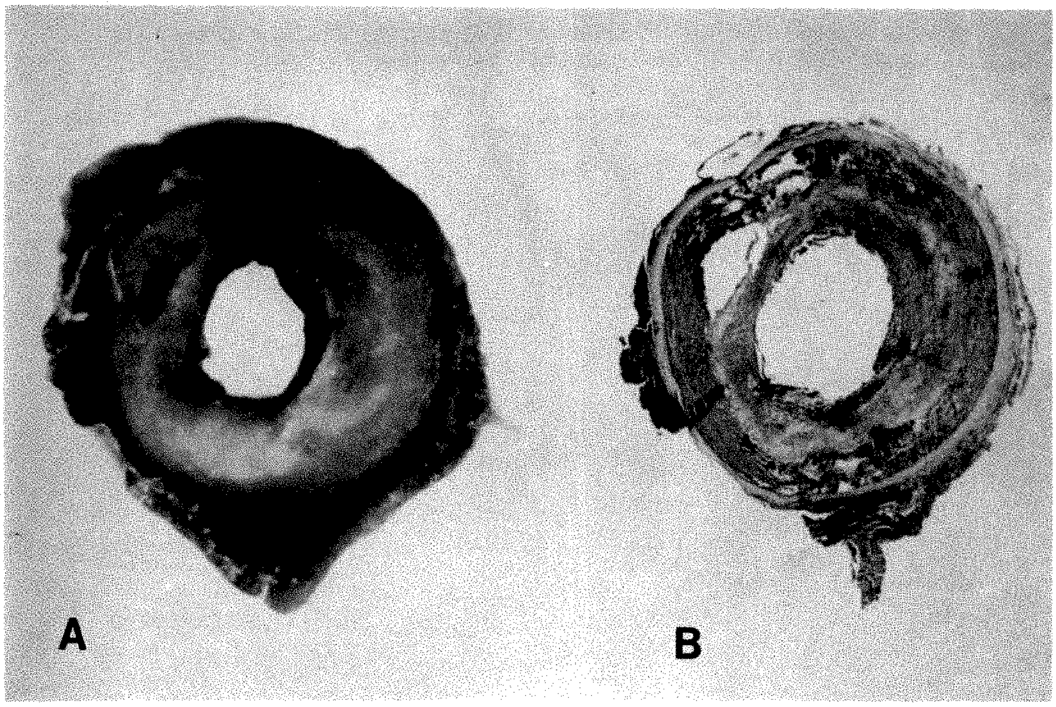
Vascular

Lasers have been employed experimentally and clinically in microvascular welding and recanalization of atherosclerotic vessels. In microvascular welding, vessels of 1 mm in diameter or less are joined using spot weld



FIGS. 19A and B. *A.* Autopsy specimen of atherosclerotic femoral artery. *B.* Immediately following argon laser vaporization of atheroma. Note the increase in luminal diameter but thermal injury, arterial wall.

techniques or by application of external supports of laser-coagulated collagen or blood.[90] Such techniques appear to reduce foreign body inflammatory action, preserve normal vascular anatomy and luminal diameter, and allow growth of vessels without stenosis, which may be particularly advantageous in children.[91]

The ability to transmit laser energy through small flexible fibers has suggested application use for recanalization of occluded atherosclerotic arteries by catheter or endoscopic techniques.[92] *In vitro* studies have shown that atherosclerotic plaque can be vaporized with various lasers, especially where the chief component is cholesterol (Fig. 19).[93] Calcified plaque is more difficult to ablate, however.[94] Several preliminary case reports are available utilizing either Nd:YAG or argon laser to recanalize occluded femoral arteries. Vessels in 16 patients studied in one series were recanalized with two perforations. No major hematomata occurred despite full anticoagulation with heparin.[95] In another series of 51 attempted femoral artery procedures using a thermal laser tip, nine were immediate failures due to either inability to recanalize the lesion or to thrombosis. Initial patency rate of 83% slowly dropped to 73.2% at the end of a 21-month period.[96]

Due to injury and perforation of arterial wall, selective ablation of plaque with or without the use of exogenous photosensitizers seems vital before advances can be made. The effect of the debris created by vaporization of plaque on the peripheral vascular bed has been studied and appears to be minimal in extremities.[97] The effect of such debris on critical peripheral beds such as brain, kidney, and myocardium have not been fully studied.

Photodynamic Therapy

Photodynamic therapy (PDT) is a new procedure involving known photobiologic principles that may be useful in the treatment of various tumors and disease processes.[98] Current laser applications depend upon absorption of laser energy by naturally occurring molecules in tissue such as hemoglobin or melanin (endogenous chromophores). It has been known since 1903 that various drugs could be introduced intravenously that would bind selectively to tumors or associated vascular beds.[99] Hematoporphyrin derivative (HPD) has been one of the agents most widely studied in this regard.[100] After a period of 24–48 hours after injection, much of the photosensitizer (HPD) is cleared from normal cells and organs but is retained in high concentrations in tumors, plaque, inflammatory tissue, and certain bacteria. After the clearing period, light of appropriate wavelength to activate the sensitizer is applied directly to the tumor by an interstitial fiber or by endoscopic techniques. While some thermal reaction may occur, this is minimal. The chief effect of the photosensitizer is to initiate a chemical reaction in target cells, which results in fluorescence and the formation of singlet oxygen with associated phototoxicity and selective tumor damage (Fig. 20).[101]

Much of the initial clinical work using photosensitization has been carried out in recurrent carcinoma of the breast with cutaneous metastasis. Carruth and Dougherty reported initial reduction in tumor size in 60–70% of patients so treated.[102] In carcinoma of the bronchus, Hayata et al. treated 35 patients with PDT where conventional surgery was not possible with good reduction in tumor mass or palliation reported in 30–40% of patients.[103] A summary of the literature of current clinical results appears in Table 2.

Another unique element in photosensitization is that photosensitizer can be activated to fluoresce when the appropriate wavelength light is applied (Fig. 21). This has been employed in the bronchoscopic identification of early tracheobronchial carcinoma.[103] These techniques might provide for early tumor diagnosis utilizing fluorescence followed by phototherapy to cause selective destruction of sensitized tumor cells.

TABLE 2. *Summary of Response of Various Tumors to PDT (to 1984)*

Tumor Type	No. of Patients or (Sites)	Response CR	PR	NR	Longest Follow-up to Date (yr)
Skin (met. breast, basal cell, squamous, melanoma)	(219)	(147)	(29)	(43)	4
Endobronchial					
Late stage	262	106*	136	20	1.5
Early stage	32	17	10	—	4.5
Bladder, superficial	(70)	(38)	(16)	(13)	2
Head/neck, recurrent	49	9	26	14	2
Gynecologic, recurrent	11	4	5	2	2
Esophagus, advanced	17	0	11†	6	1

CR = complete remission; PR = partial remission; NR = no remission.

* Complete opening to wall of lumen following physical removal after PDT.

† Partial relief of obstruction.

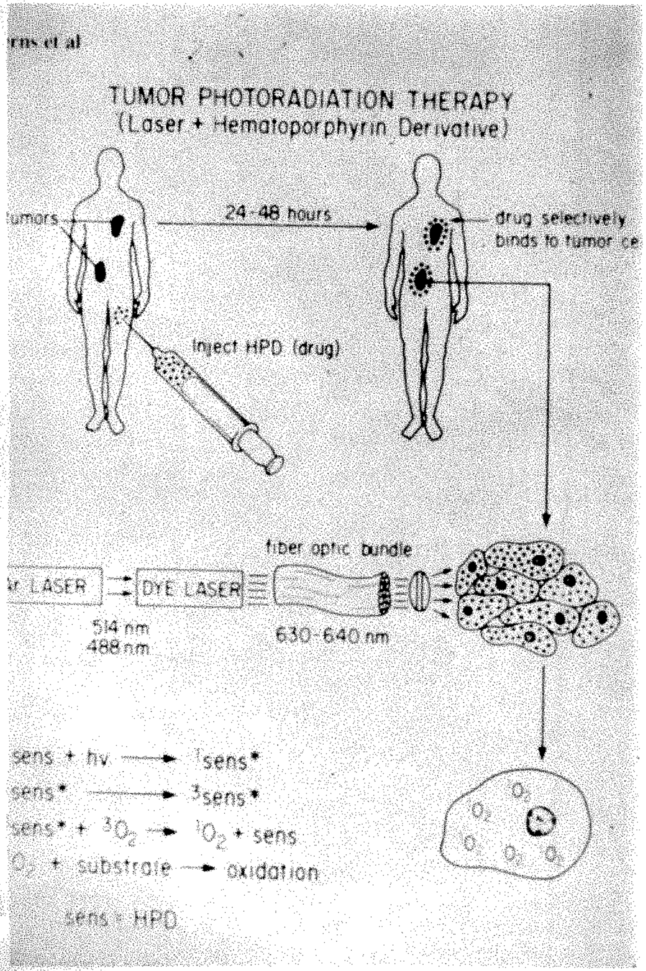


FIG. 20. Schema of PDT with hematoporphyrin derivative (after Dougherty).

Numerous new photosensitizers with greater potency and tumor selectivity are available and await appropriate preclinical studies and approvals.[104]

Discussion

The entire field of applications of lasers in general surgery is dynamic and evolving, and it requires constant critical evaluation. The field has been plagued by an inordinate amount of media attention and the usual plethora of uncontrolled enthusiastic reports by early investigators. Fortunately, well-designed trials are now becoming available to provide tenable guidance relative to indications and contraindications for application of these devices. At this point however, certain observations seem warranted:

1. Laser applications in general surgery now have achieved limited but defensible indications for certain selected procedures.
2. The use of lasers as a surgical instrument employed through endoscopes has resulted in a number of GI applications that will impact conventional incisional methods. It appears inevitable that the general surgeons of the future will need skills in at least upper GI endoscopy, colonoscopy, and choledochoscopy to utilize minimally invasive laser and other techniques.
3. The utilization of photosensitizers to identify by fluorescence and treat various tumors by phototherapy opens interesting possibilities for primary management or adjunctive treatment in association with conventional surgery.

Technologic advances promise smaller, less expensive, more reliable lasers with improved delivery devices for handheld operative microscopes or for endoscopic

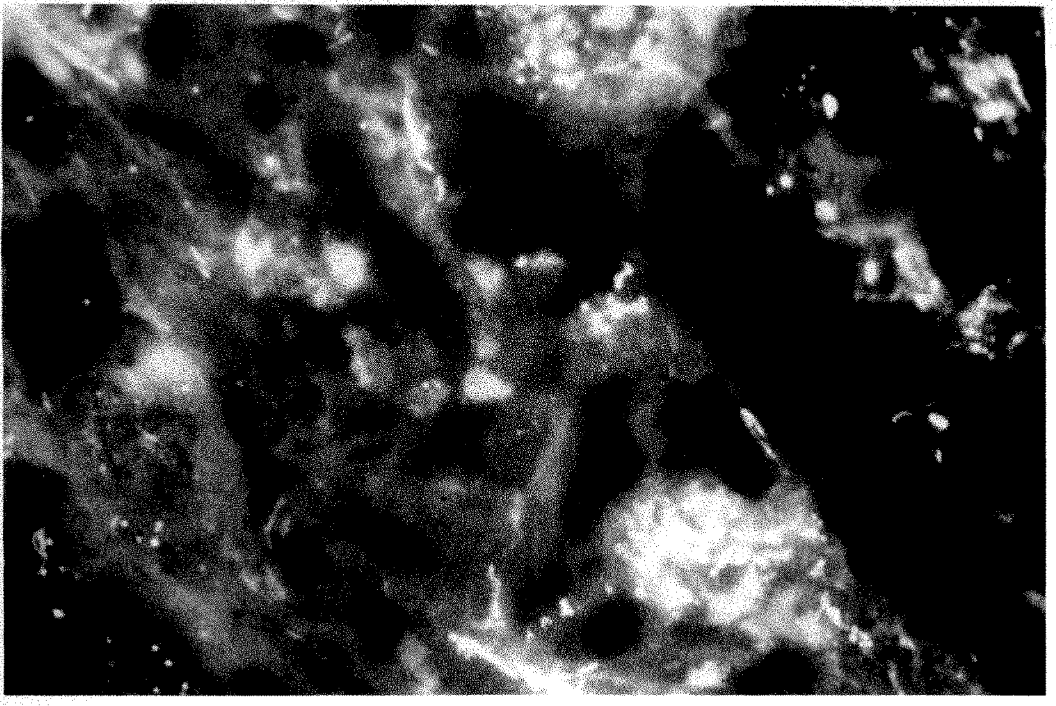

FIG. 21. Fluorescence of HPD-sensitized mouse tumor cells (scattered white spots) with 420 nm light; normal cells in background (dark areas).

use. New wavelengths and even tunable lasers will appear in the near future.

Despite the fact that membership in the American Society for Laser Medicine and Surgery recently passed the 1000 mark, not every surgeon should buy a laser. These expensive devices should be utilized only for specific indications where standard techniques are not available or are less efficacious. It is important, however, for every general surgeon to remain aware of developments in this field, which involve many new and intriguing aspects of photobiology and light tissue interactions that may prove to have surgical application.

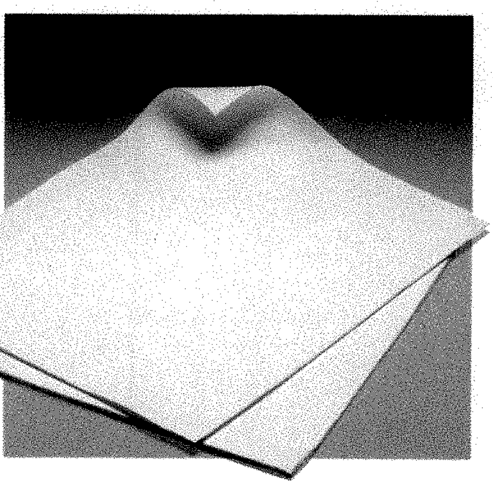
The Natural Choice



The best is not always good enough. The first choice, a patient's own tissue, cannot always be used for surgical reconstructions. When this happens the Soft Tissue Patch becomes the natural choice.

Since its introduction five years ago, the Soft Tissue Patch has performed exceptionally well in over 12,000 clinical cases. These cases include a wide variety of applications:

- Abdominal wall defects
- Large and small hernia repairs
- Thoracic wall defects
- Related pediatric reconstructions
- Rectal prolapse
- Vaginal prolapse
- Gastric banding

The excellent performance of the Soft Tissue Patch is due to its:

- soft, conformable nature
- high, balanced strength
- resistance to the spread of infection
- biocompatibility
- lower incidence of visceral adhesions/tissue erosion

GORE-TEX Soft Tissue Patch, the superior biomaterial, the natural choice.

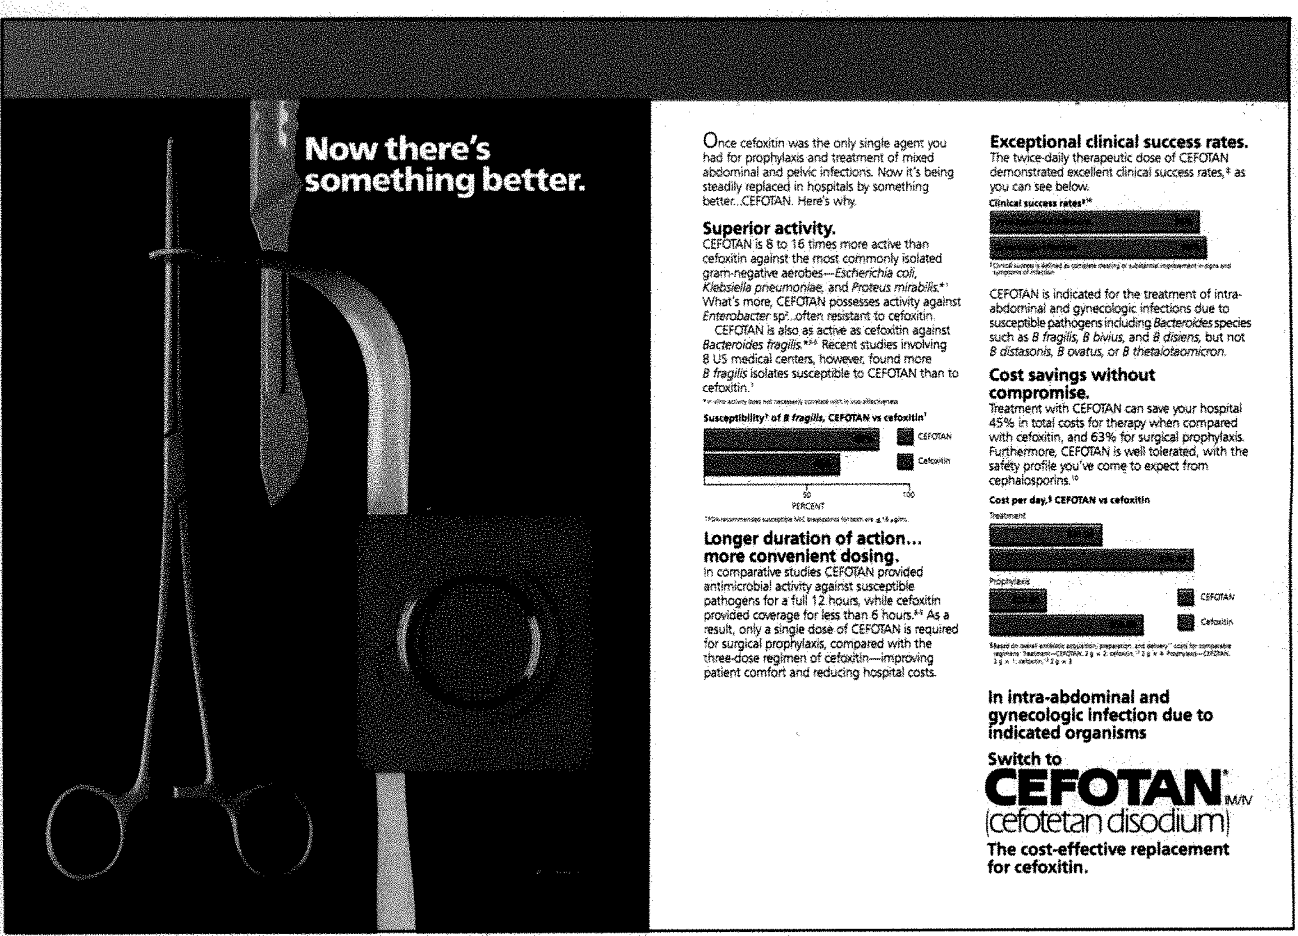
We said.[1]



Now there's something better.

Once cefoxitin was the only single agent you had for prophylaxis and treatment of mixed abdominal and pelvic infections. Now it's being steadily replaced in hospitals by something better...CEFOTAN. Here's why.

Superior activity.

CEFOTAN is 8 to 16 times more active than cefoxitin against the most commonly isolated gram-negative aerobes—*Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis*.*[1] What's more, CEFOTAN possesses activity against *Enterobacter* sp[2]...often resistant to cefoxitin.

CEFOTAN is also as active as cefoxitin against *Bacteroides fragilis*.*[3-6] Recent studies involving 8 US medical centers, however, found more *B fragilis* isolates susceptible to CEFOTAN than to cefoxitin.[7]

Susceptibility† of *B fragilis*, CEFOTAN vs cefoxitin[7]

CEFOTAN
Cefoxitin
50
100
PERCENT

Longer duration of action... more convenient dosing.

In comparative studies CEFOTAN provided antimicrobial activity against susceptible pathogens for a full 12 hours, while cefoxitin provided coverage for less than 6 hours.[8,9] As a result, only a single dose of CEFOTAN is required for surgical prophylaxis, compared with the three-dose regimen of cefoxitin—improving patient comfort and reducing hospital costs.

Exceptional clinical success rates.

The twice-daily therapeutic dose of CEFOTAN demonstrated excellent clinical success rates,‡ as you can see below.

Clinical success rates‡[10]

CEFOTAN is indicated for the treatment of intra-abdominal and gynecologic infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis*, *B bivius*, and *B disiens*, but not *B distasonis*, *B ovatus*, or *B thetaiotaomicron*.

Cost savings without compromise.

Treatment with CEFOTAN can save your hospital 45% in total costs for therapy when compared with cefoxitin, and 63% for surgical prophylaxis. Furthermore, CEFOTAN is well tolerated, with the safety profile you've come to expect from cephalosporins.[10]

They said.[2-9]

for treatment in obstetrics and gynecology

"Twice-daily administration of cefotetan is a highly effective single agent for the treatment of mixed aerobic-anaerobic infections in obstetric and gynecologic patients."[2]

2. Sweet RL, Gall SA, Gibbs RS, et al: Multicenter clinical trial comparing cefotetan versus moxalactam or cefoxitin as therapy for obstetric and gynecologic infections. *Am J Surg,* submitted for publication.

"Cefotetan plus doxycycline was demonstrated to be an effective and safe regimen for the treatment of acute PID as measured by early clinical response."[3]

3. Sweet RL, Schacter J, Landers DV, et al: Treatment of hospitalized patients with acute pelvic inflammatory disease: Comparison of cefotetan plus doxycycline and cefoxitin plus doxycycline. *Am J Obstet Gynecol,* submitted for publication.

for treatment in intra-abdominal infection

"98% (93/95) of cefotetan patients and 95% (41/43) of cefoxitin patients had complete resolution or improvement of their signs and symptoms of intraabdominal infection."[4]

4. Wilson SE for the Multicenter Study Group: Cephalosporin therapy in intraabdominal infections: A multicenter randomized comparative study of cefotetan, moxalactam and cefoxitin. *Am J Surg,* submitted for publication.

for prophylaxis in obstetric and gynecologic surgery

"In this evaluation, cefotetan administered in a single dose of 1 gm was more effective as a prophylactic agent than multiple, 2-gm doses of cefoxitin in reducing infectious morbidity in...cesarean section patients."[5]

5. McGregor JA, Gordon SF, Krotec J, et al: Results of a randomized, multicenter, comparative trial of a single dose of cefotetan versus multiple doses of cefoxitin as prophylaxis in cesarean section. *Am J Obstet Gynecol,* submitted for publication.

"Uterine tissue concentration was...well above the minimum inhibitory concentrations required for most gram-positive anaerobes as well as Bacteroides fragilis."[6]

6. Berkeley AS, Freedman KS, Ledger WJ, et al: Comparison of cefotetan and cefoxitin for abdominal and vaginal hysterectomy. *Am J Obstet Gynecol,* submitted for publication.

for prophylaxis in general surgery

"Cefotetan administered as a single 2-gm preoperative dose was as safe and effective as multiple doses of cefoxitin."[7]

7. Jagelman DG, Fabian TC, Nichols RL, et al: Single-dose cefotetan vs. multiple-dose cefoxitin as prophylaxis in colorectal surgery. *Am J Surg,* submitted for publication.

as a cost-effective replacement for cefoxitin

*"Cefotetan therapy cost less than cefoxitin therapy for all types of infections."**[8]

8. Sochalski A, Sullman S, Andriole VT: Cost effectiveness study of cefotetan versus cefoxitin and cefotetan versus combination antibiotic regimens. *Am J Surg,* submitted for publication.

"Cefotetan can provide significant cost savings with neither a compromise in therapeutic effectiveness nor an increased risk of toxicity."[9]

9. Hemsell DL, Wendel GD, Gall SA, et al: Multicenter comparison of cefotetan and cefoxitin in the treatment of obstetric and gynecologic infections. *Am J Obstet Gynecol,* submitted for publication.

*CEFOTAN is indicated for the treatment of intra-abdominal and gynecologic infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis, B bivius,* and *B disiens,* but not *B distasonis, B ovatus,* or *B thetaiotaomicron.*

We all agree.

CEFOTAN® IM/IV
(cefotetan disodium)

Does so much for so much less than cefoxitin

Please see next page for brief summary of prescribing information.

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV
(cefotetan disodium)

Does so much for so much less than cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus.*†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

† Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

CEFOTAN® (cefotetan disodium)

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

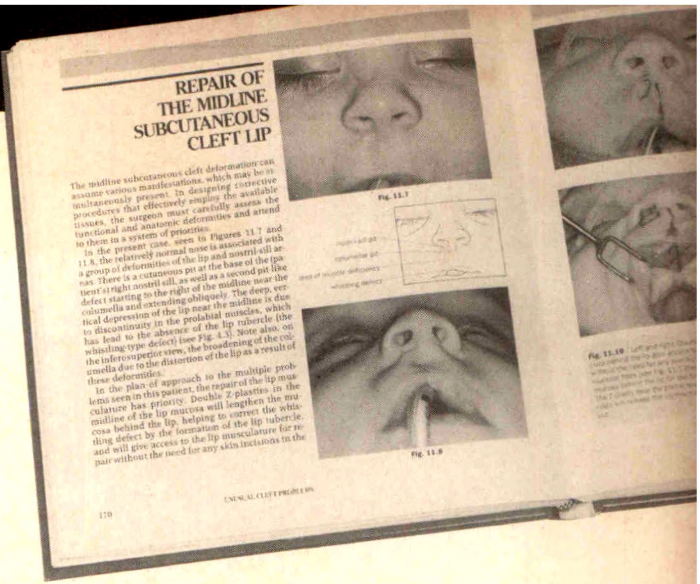
A vivid, FULL COLOR ATLAS...



REPAIR OF THE MIDLINE SUBCUTANEOUS CLEFT LIP

The midline subcutaneous cleft deformation can assume various manifestations, which may be simultaneously present. In designing corrective procedures that effectively employ the available tissues, the surgeon must carefully assess the functional and anatomic deformities and attend to them in a system of priorities.

In the present case, seen in Figures 11.7 and 11.8, the relatively normal nose is associated with a group of deformities of the lip and nostril-sill areas. There is a cutaneous pit at the base of the patient's right nostril sill, as well as a second pit-like defect starting to the right of the midline near the columella and extending obliquely. The deep, vertical depression of the lip near the midline is due to discontinuity in the prolabial muscles, which has lead to the absence of the lip tubercle (the whistling-type defect) (see Fig. 4.3). Note also, on the inferosuperior view, the broadening of the columella due to the distortion of the lip as a result of these deformities.

In the plan of approach to the multiple problems seen in this patient, the repair of the lip musculature has priority. Double Z-plasties in the midline of the lip mucosa will lengthen the mucosa behind the lip, helping to correct the whistling defect by the formation of the lip tubercle, and will give access to the lip musculature for repair without the need for any skin incisions in the

Techniques in CLEFT LIP, NOSE AND PALATE RECONSTRUCTION

...show you the art of reconstructive plastic surgery for children born with cleft deformities

By Donald I. Kapetansky, M.D.

Foreword by D. Ralph Millard, Jr., M.D.

250 Beautiful, full-color illustrations...

. . . show you some of the most effective and efficient procedures in use today to correct cleft deformities in children. Sequential photographs of operations show each step of repair. Clear, close-up photographs show cleft deformities from various angles to help you fully understand the patient's condition. Detailed line drawings, full-color schematic diagrams, and explanatory text accompany the photographs and clarify important aspects of the deformities and the surgical techniques employed to correct them.
